HOMER'S SENSE OF COLOUR

Le Sens des Couleurs chez Homère. By Dr. Alb. de Keersmaecker. Part I., xii. + 152 pp. (London: Trübner, 1885.)

THIS appears to be Part I. of a monograph on the colour-sense developed in ancient times, although chiefly based on the language of the Homeric poems. It is to a large extent a criticism of the essays of Mr. Gladstone and Dr. Magnus (of Breslau) on this subject. It is generally admitted that the colour-nomenclature of the Homeric poems is far less copious and less precise than that of modern times. Various theories have been proposed about this. The author represents (p. 22, &c.) Mr. Gladstone's view to be that Homer's *perception* of colour was ill-defined, and that his so-called colour-terms are often really descriptive of luminosity rather than colour. And he describes (p. 6, &c.) that of Dr. Magnus similarly, with the addition that the human eye was in those days less perfect in colour-perception than now, and has gradually improved to its present state.

After a lengthy criticism of these and other theories, the author's conclusions are briefly that there is no evidence of any improvement in the human eye itself during these ages, and that the progress that had taken place is solely one of human knowledge of colour: also that Homer's colour-terms are probably often vague, but not more so than is admissible in poetry.

As to evolution, however, the author goes much further: he lays down broadly (p. 32) that no change has taken place in any organ in any species, and most certainly not in man. It is strange that he also expresses himself as a follower of Darwin. After this it will not seem strange that the general argument is not particularly convincing: the mode of argument, too, is not pleasant; in fact the author pleads guilty to a certain sharpness of manner (*acescence de la forme*) in his criticism of persons.

Waiving however the form, there is much in the matter that is interesting. A short account (9 pages) is first given of what is known of Homer's life, and it is argued that Homer—as being an illegitimate child—was constitutionally liable to the infirmity of blindness traditionally ascribed to him: it is fairly urged by some that this blindness, coupled perhaps with *colour-blindness*, may itself be responsible for some of the uncertainty attached to Homer's colour-terms; but the conclusion is that there is no evidence of colour-blindness.

As to the misuse (?) of colour-names sometimes ascribed to Homer, the author points out (with numerous quotations) that the usage of modern French and English poets is often, to say the least, inexact, so that it is absurd to expect exactitude of application in ancient poetry.

Among the detailed criticisms on Mr. Gladstone's essays may be noticed the following:—Exception had been taken to the use of the word φοῖνιξ (usually translated *red*) as descriptive of a horse; hereon it has been urged (by Mr. Prior in NATURE) that this word should here be translated *Phœnician;* but, if this be really a colour-term in this place, why not translate it as a *bay* or *chestnut* (horse) if the term *red* jars on the English ear? Again, surely a poet may describe a (mythical) serpent as δαφοινός (red ?), and the (mythical) ambrosia as ῥοδόεις (rosy ?) without being called to account. In one case (Odys. B. VI. v. 163), where the use of φοῖνιξ as a colour-term had been objected to, the author explains that its other meaning, *palm-tree*, makes sense of the passage. Special exception is taken to Mr. Gladstone's interpretation of αἴθοψ, which the author considers to be not a colour-term but a word descriptive of combustion, so covering a wide range of meanings, *e.g.* fiery, glowing, smoky, golden, &c.

The Homeric expression οἴνοψ applied to the sea—hitherto far from clear—receives a new explanation from a traveller in the Ægean, viz. that that sea has at times a blood-red appearance with a red horizon all round. In commenting on the word χλωρός, which seems to mean both *green* and *fresh* or vigorous, the author endeavours to connect the syllable ι with the meaning of vigour, *e.g. harit* (Sanskr.), *sairit* (Zend), ἶφι (Greek), *vi* (Lat.), (to which may surely be added the English *might*), but the connection seems very slight; in fact the syllable ι recurs in many terms expressing weakness or smallness, *e.g.* μικρός, *minimus*, *slight*, *schlimm*, *weich*, *faible*.

The remarkable fact is brought to notice that the term *sky-blue* is almost unknown in the ancient writings of any Asiatic people, *e.g.* in the Vedic hymns, in the Zend-Avesta, in the Old Testament, in Hebrew writings generally, and in Homer and Hesiod; the epithets applied to the sky being expressive of its vastness, depth, purity, brilliancy, &c., but not of its colour. A similar want of a precise colour-term is shown to exist in many modern barbarous languages. But it does not seem warrantable to conclude that sky-blue was a colour unknown to these peoples; indeed sky-blue pigments have been found (p. 37) at both Memphis and Thebes.

A part of Dr. Magnus's theory of the evolution of the colour-sense is that the eye acquired the power of recognising different colours in the order of their luminosity; but the order which he seems to assign (p. 71), viz. red, yellow, &c., is certainly not that of their luminosity. The physiological and emotional effects of colours on men and animals are noticed in this connection. Thus red is known to excite bulls and turkeys: the experiments of M. Paul Bert on the small crustacean Daphnia are quoted; when placed in a solar spectrum they congregate most thickly in the orange to green region, which is also the most luminous region. Goethe's speculations on the effects of colour on the emotions of mankind are noticed at length. A curious "colour-treatment" (chromo-photothérapie) proposed for the insane is also mentioned, which consists in placing the patients amidst surroundings of a tint supposed to be capable of exciting healthful effects: thus red is said to excite, blue and violet to sadden, green to soothe. The results of this treatment do not seem to have been very definite (pp. 78, 79).

The comparative philology of colour-terms takes up—as might be expected—much of the work; the author has spared no pains in endeavouring to trace out the meanings of Homer's colour-terms by the help of the related words in other languages. As to the uncertainties of this process, take the words related to *blue* as an instance. Mr. L. Geiger's opinion is quoted (p. 50) that the modern European words *blue*, *blae*, *blau*, *blå*, *bleu*, &c. (English, Scotch, German, Danish, French), now meaning *blue*, meant *black* in early Europe, whilst another (p. 101) connects them with words conveying the idea of brightness, *e.g. briller*, *blanc*, *blink*, *bleach*, *blank*.

The author promises a further instalment of this essay, in which the evidence from the fine arts, pottery, and dyers' work, and that from morphology and physiology are to be set forth; also a full statement of conclusions.

ALLAN CUNNINGHAM (Major, R.E.)

OUR BOOK SHELF

The Journal of the Engineering Society of the Lehigh University, March, 1886.)

THE practice of forming engineering societies in universities where engineering is taught is an exceedingly good one, and should receive every encouragement and help from the authorities. In fact every college should have its society. The meetings give the students an opportunity of discussing interesting engineering works, and give them a greater interest in the subject-matter taught in the class-room. These junior engineering societies, if I may so call them, ought not to be only found in colleges, but all large engineering works should have a society of their own, the members of which should include those of the pupils, apprentices, and men who are anxious to improve themselves by the reading and discussing of papers prepared in rotation by the members themselves. Visits to other works might also be arranged. No doubt the formation of such societies may seem very hard to accomplish, but in most works there will be found men willing and anxious to form such societies and to keep them going until their utility is recognised.

The *Journal* before us contains several articles of an interesting nature, the first being by Prof. Merriman on "The Internal Work and the Deflection of Beams"; the second article gives an account of "Boring the Big Aqueduct" for the New York water-supply from Croton Lake. We next have a short notice on technical education in Mexico, followed by a very good account dealing with "The Requisites of a Successful Engineer.'

After notices on "Mine Water Formations" and "The Foundations of the Washington Monument," the *Journal* concludes with a condensed report dealing with the measurements necessary to ascertain "the velocity and discharge of the Lehigh River about Bethlehem."

Taken as a whole the contents of this *Journal* are disappointing from a professional point of view, Prof. Merriman's article on the deflection of beams being excepted. The descriptions are much too general and popular; the subjects are not treated with that accuracy demanded by an engineering article, and are written in a style more fitted for the columns of a daily paper than a journal published by an engineering society.

Fresenius's Quantitative Analysis. Parts I. and II. Vol. II Translated by C. E. Groves, F.R.S. From New Edition of Fresenius commencing in 1877. (No date)

IT is a great pity these books cannot be pushed forward much faster. The plan adopted by many German authors of sending out books in "Lieferungen" has some advantages, but generally these are more than balanced by the time allowed to elapse between each part. This slowness on the part of authors makes it somewhat unpleasant for a translator, who must of necessity be still somewhat later. In this particular instance, however, the translator has improved on the time by introducing or referring to methods not in the original, but it might have been carried further. The original does not contain anything about Victor Meyer's methods of vapour-density determination, and the translator has also refrained from noticing these methods. There may be some reason for this, but we think at least the methods might have been mentioned, as they are simpler to perform than any other, and do not fall behind any in accuracy.

The whole of Part I. and a small portion of Part II. is taken up with analysis of organic bodies; the remainder of Part II. is on the analysis of potable and spring waters. &c. If an index or table of contents had been added, it would have rendered the English edition more practical.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Protective Influence of Black Colour from Light and Heat

IN NATURE, vol. xxxiii. p. 559, a correspondent refers to the effect of blackening the skin round the eyes as a protection against the glare of strong sunlight. Probably the practice has good scientific grounds.

The shape of the orbit at once suggests the reflecting cone of a thermopile, with the eyeball centred on its axis in the position of the pile, but of course much less deeply placed. The cone is, in this case, oblique, the maximum slant side being internal, *i.e.* towards the nose, and the minimum slant side external. A plane through the outer orbital angle, and perpendicular to the axis, will be pretty nearly coincident with the tangential plane of the eyeball at the anterior end of its antero-posterior diameter, and there will be a considerable part of the nasal surface of the cone in front of that plane. This part will act as a reflecting surface, and concentrate the rays upon the eyeball. Probably variations of complexion will not much affect the reflecting power of this surface, seeing that the difference in the skin of black and of white races is mainly a difference in the amount of pigment in the rete mucosum, and not in the superficial parts of the epidermis.

It is evident that rays reflected from the ground, and from objects of no great altitude, are the rays which will have the greatest chance of striking the eye after reflection from the sides of the orbital cone. The direct rays of the sun in tropical countries will, during the hottest part of the day, be too nearly vertical to take this course. Now it would seem that it is in the case of intense light reflected from rocks, snow, &c., that the blackening has been found useful.

Whether to any appreciable extent the amount of light entering the eye is increased by the shape and projection of the orbit is a different question. For here it is not enough that the rays should be concentrated upon the eyeball. They must enter the pupil. Nevertheless, it would seem from observations made for another purpose upon the pupil-reflex, that the diameter of the aperture is increased by blackening the skin round the orbit, say by means of a piece of black cloth with an elliptical hole in it for the eye, the light of course being kept of constant intensity.

On the Form of Mole-Hills Thrown up under Snow

MOLES must have an opportunity of getting to the surface here and there to dispose of the results of their excavations. When they meet with a deep-laid hard road they come out and cross it. When frost has bound the soil into an impenetrable cake they sometimes come out of the ground, and, travelling away to seek a place more suitable for their operations, are unable to find their way back or to burrow into the frozen soil in another place,

and so they get killed in considerable numbers. When there is a little snow on the ground, protecting it from the frost, the moles come to the surface as usual, and throw up mounds of earth under or through the snow. But, when deep-drifted snow has covered the ground, the mole-hills under it are found to be arranged in more or less symmetrical ridges of uniform height and breadth, as represented in the sketch. It would appear that the moles in these circumstances make galleries about the size of their own bodies on the surface of the turf in the bottom of the snow, into which they push the earth to be disposed of, finding it easier to make these small tunnels than to raise the usual mound of earth under the superincumbent snow-drift. The severe winter just over has caused the snow-drifts to lie long in the north of England, where examples of this peculiar form of mole-hill may be commonly seen on the Fells.

Cambridge THOS. MCKENNY HUGHES

Protective Imitation

I HAVE been watching for hours with great interest what I believe to be a very curious instance of protective imitation. A large old thrush has been, all that time, trying to make itself look like a serpent, and succeeding remarkably well. The object appears to be to frighten away a smaller and more active thrush—no doubt younger and with sharper ears—which seems to be getting all the worms. It appears afraid to attack its young rival, but runs towards it as if it meant to do so, and when the young one turns round and faces it, the old one crouches down so that nothing of it is seen but a crest-like back, two glaring eyes, the spotted throat, and a dark line formed by the front view of the beak and the lines at the corners of the mouth, which look very much like a serpent's mouth. If I saw the creature protruding from a bush or from the grass, I should certainly take it for a snake of some kind. The young bird looks alarmed and retreats, though just before it was ready to attack the other. No sooner has it recovered its courage and advanced to attack than the old one retreats, and resumes its serpent-like mask. There has been a little sparring in the air occasionally, just enough to show the nature of the feeling, but if allowed to do so the young one evidently would be content to feed quietly. The old thrush (I know it by a small white feather on one wing) is very much at home on this lawn, and seems to consider it as its own private domain, at all events as far as thrushes are concerned. A short time ago, when the ground was for a long time hard from frost and drought, this thrush moped about and seemed nearly starved, and at last fell upon two great clumps of yellow crocuses, and not only tore them to pieces, as if in a rage, but devoured them entirely, returning again and again to them, and gobbling up the yellow petals as a rabbit does a lettuce. At that time many birds that are usually too shy came down from the hills and strolled about the fields and lawns—snipes, plovers, &c. Two exquisite crested plovers (I think they are called) stalked about with graceful dignity for some days in a garden close by, and roosted in an old henhouse. The thrush touched no crocuses but the yellow ones, and no other bird did so. I should be glad to know if the resemblance to a serpent has been observed by any one else. J. M. H.

Sidmouth, April 19

P.S.—It may be thought that the crouching is only a preparation for a spring, but it does not suggest that to the eye, and it is not followed by a spring. If it really is a fact and not a fancy, the instincts of imitation and of fear in this case must be a very ancient inheritance indeed.

Iridescent Clouds

THIS evening at sunset there was here a fine instance of iridescent clouds. About 7 I drew the attention of my companion to some remarkable clouds; three long arms of stratus of peculiar texture, like pulled-out cotton-wool, and of striking colour, blue-black and silver, stretched nearly to where the sun had gone down behind a hill. At 5 minutes past 7 a detached portion of this cloud assumed lovely iridescent colours like bright mother-of-pearl. This gradually died away, but other portions assumed the same tints. At 7.30 the tints vanished. Wind, south to south-west.

Glencar, Kerry, April 26 J. G. GRENFELL

MADRAS MAGNETICAL OBSERVATIONS[1]

WE are indebted for the present volume to Mr. Pogson, the Government Astronomer at Madras, from whose introductory remarks we learn that he is not yet at the end of his editorial labours.

[1] "Magnetical Observations made at Madras in the Years 1851-1855, under the Superintendence of Mr. W. S. Jacob." Edited by Mr. N. R. Pogson, Government Astronomer. (Madras: Lawrence Asylum Press, 1884.)

Mr. Pogson intends as soon as possible to continue his work, and the greatest praise must be given to this distinguished astronomer for his persistent efforts to complete the records of his Observatory. But what can be thought of a system of administration under which observations are reduced about half a century after they are made? If this were the only instance of such a monstrous delay it would be bad enough, but we seem destined to have another instance, no less flagrant. The late Mr. John Allan Broun finished his work at the Trevandrum Observatory in 1864, and as yet only the first volume of his reductions has seen the light. Here the Observatory has been discontinued, and we do not know that any one has come forward to complete the labours of Mr. Broun, so that the publication of the remaining volumes seems to be adjourned indefinitely. Surely there is something in this system which requires putting right.

Mr. Pogson tells us in his introduction that the vertical force results were never entitled to any confidence, especially before March 1853, when, for the first time, the needle was placed nearly perpendicular to the magnetic meridian, agreeably to the directions given in the report of the Royal Society. Our readers are probably aware that at the present moment a Committee of the British Association is engaged in discussing magnetic observations, and they are anxious to bring together all reasonably good determinations of the solar-diurnal variations of the three magnetic elements for as many places as possible.

It may therefore be of interest, especially after the above remark by Mr. Pogson, to apply some sort of preliminary test to the Madras observations. I shall therefore compare them with the similar results obtained at Bombay, and discussed by Mr. C. Chambers in his recent elaborate and excellent volume.

In the following table we have in the first place a comparison of the solar-diurnal variations of declination at the Colaba Observatory, near Bombay, and at Madras. For the purpose of this comparison it is unnecessary to give the scale values or to exhibit all the months. We have therefore limited our comparisons to a mean of the three months, November, December, and January, and also of the three months, May, June, and July.

TABLE I.—*Comparison of the Solar-Diurnal Variations of Declination at Bombay and at Madras*

Bombay civil time (noon = 12) h. m.	Mean of Nov., Dec., Jan.	Mean of May, June, July	Madras civil time (noon = 12) h. m.	Mean of Nov., Dec., Jan.	Mean of May, June, July

1 ,,	+ 17	+ 37	1 ,,	+ 2	+ 25
2 ,,	+ 4	+ 44	2 ,,	− 3	+ 31
3 ,,	− 12	+ 46	3 ,,	− 12	+ 30
4 ,,	− 33	+ 51	4 ,,	− 23	+ 34
5 ,,	− 54	+ 85	5 ,,	− 36	+ 60
6 ,,	− 67	+ 206	6 ,,	− 48	+ 120
7 ,,	− 74	+ 272	7 ,,	− 40	+ 129
8 ,,	− 11	− 249	8 ,,	− 4	+ 91
9 ,,	+ 48	+ 128	9 ,,	+ 10	+ 21
10 ,,	+ 33	− 30	10 ,,	− 4	− 47
11 ,,	− 26	− 165	11 ,,	− 10	− 101
12 ,,	− 34	− 245	12 ,,	0	− 121
13 ,,	+ 8	− 236	13 ,,	+ 12	− 105
14 ,,	+ 28	− 184	14 ,,	+ 14	− 76
15 ,,	+ 31	− 105	15 ,,	+ 22	− 40
16 ,,	+ 26	− 34	16 ,,	+ 23	− 12
17 ,,	0	0	17 ,,	+ 12	0
18 ,,	+ 1	− 6	18 ,,	+ 16	− 13
19 ,,	+ 19	− 45	19 ,,	+ 19	− 22
20 ,,	+ 17	− 48	20 ,,	+ 13	− 19
21 ,,	+ 14	− 33	21 ,,	+ 9	− 9
22 ,,	+ 18	− 15	22 ,,	+ 10	0
23 ,,	+ 24	+ 5	23 ,,	+ 10	+ 8

Now it will, we think, be seen from Table I. that at both stations the type as well as the range of the solar-diurnal variation is very different for the two groups of months. It will likewise be seen that the peculiarities of the summer variation are very much alike at both stations, and that the peculiarities of the winter variation are also very much alike. Thus the comparison is favourable to the accuracy of the observations at both stations.

Let us now turn to the force components. In Table II. we have a comparison of the horizontal and vertical force variations at the two stations for the two months, June and December.

TABLE II.—*Comparison of the Solar-Diurnal Variations of the Horizontal and Vertical Force at Bombay and at Madras*

Bombay civil time (noon = 12) h. m.	Horizontal force June	Horizontal force Dec.	Vertical force June	Vertical force Dec.

9 ,,	+ 658	+ 573	− 1329	− 938
10 ,,	+ 873	+ 740	− 1688	− 1247
11 ,,	+ 876	+ 730	− 1926	− 1043
12 ,,	+ 716	+ 580	− 1631	− 1246
13 ,,	+ 483	+ 354	− 1090	− 1304
14 ,,	+ 194	+ 160	− 389	− 872
15 ,,	− 66	+ 15	+ 60	337
16 ,,	− 211	− 91	+ 241	− 289
17 ,,	− 281	− 185	+ 30	+ 23
18 ,,	− 319	− 256	+ 426	+ 75
19 ,,	− 338	− 326	+ 555	+ 152
20 ,,	− 323	− 369	+ 596	+ 280
21 ,,	− 336	− 374	+ 640	+ 376
22 ,,	319	− 341	+ 779	+ 585
23 ,,	− 311	− 314	+ 991	+ 747

It will be seen from this table that at both stations and for both components the type for June is nearly the same as that for December, the chief difference being in range. Also that the type at the one station is very similar to that at the other. The most marked difference between the two stations is for the vertical force, the range of this element in December bearing a smaller proportion to its

range in June at Bombay than at Madras. To investigate this point it will be desirable to give the comparative ranges for the various elements for the various months at the two stations. This is done in the following table.

TABLE III.—*Ranges for the Various Months of the Diurnal Variations of the Three Elements at the Two Stations*

	Bombay			Madras		
Month	Declination	Hor. force	Vert. force	Declination	Hor. force	Vert. force
January ...	162	389	167	91	1318	3414
February ...	117	507	120	64	1585	3778
March ...	263	571	175	104	1785	4847
April	392	576	216	218	1851	6273
May	486	473	265	243	1522	4198
June	480	434	257	260	1214	2917
July	468	439	263	249	1218	2445
August ...	545	423	301	273	1101	3203
September...	550	407	365	282	1331	6401
October ...	258	437	213	110	1595	5163
November...	103	414	91	73	1362	3633
December...	136	356	89	86	1114	2280

From this table it will be seen that for both stations there is a smaller maximum of declination range about May or June, and a larger maximum in September, while the most decided minima are in November and February for both stations. Again, there is a maximum of horizontal force range for both stations in April, and also in October, while the minima are at Bombay in September and December, and at Madras in August and December.

Finally, at Bombay there is a smaller maximum of vertical force range in May and a larger in September, while at Madras these occur in April and September. The most pronounced minimum of vertical force is in December for both stations.

It would thus appear that there is a very striking likeness between the variations of the three elements at the two stations, and that, notwithstanding Mr. Pogson's remark about the vertical force instrument, its results do not appear to be without value in a comparison of the above nature.

BALFOUR STEWART

PLANTS AND THEIR DEFENCES

A CONSTANT struggle for existence, the consequence of the enormous increase in the numbers of the individuals of almost every species, is the fate of nearly every organism, both animal and vegetable. Some have to sustain the attacks of others which are directly antagonistic to them, and which regard them as prey; in the case of others the struggle is rather one to live in the face of adverse conditions or peculiarities of environment, so that the different organisms are not directly hostile, but each affects its neighbour injuriously by adapting itself more readily to the changing surroundings, and so diminishing the other's power of obtaining nutriment, sunlight, or whatever other condition may be the object of their competition. Thus have been developed in the different competitors different features of their constitution—many perfecting powers of active assault, others facilities for active or passive defence. The last-named is particularly the feature found in the vegetable kingdom. The want of locomotion prevents any aggressive movement of the individual, and hence success in the struggle can only be secured by more complete adaptation to environment than its competitors can show, or by protective mechanisms guarding the individual from the assaults of organisms inclined to prey upon it. These mechanisms exhibit very great variety, and their object often seems obscure till they are looked at in the light of the environment of the plant, the conditions of its life, and the enemies against which it has to contend. The specially-exposed points of attack are three: the succulent leaves and shoots or the attractive fruits are assailed by animals in search of food; the honey secreted by the flower to allure to it the particular insect adapted to bring about properly the process of fertilisation attracts also other insects whose presence is useless for such purpose, and which therefore are only robbers; while the fertilising pollen is itself the object of desire on the part of others which are equally unable to apply it to its legitimate purpose.

The protective mechanisms of plants, therefore, so far as they are directed against aggressive animals, are to be looked for mainly in the neighbourhood of the young growing parts or the reproductive organs. Not exclusively, however, but generally the older vegetative parts are defended by their own inherent qualities, such as their hardness or wiriness, which keep them from being suitable for the food of their assailants. Such young growing parts in many plants, particularly those growing in exposed regions, are plentifully supplied with thorns, spines, or prickles, rendering them in many cases extremely formidable. The thorns or prickles may be produced on almost all the vegetative organs, and may be merely epidermal structures, or much stronger in composition, containing considerable developments of woody tissue. These thorny plants are most noteworthy in desert countries, some that are met with there, notably the so-called "wait-a-bit" thorn of Africa, having spines of immense length, and being quite impenetrable by man or beast. Cases are not of infrequent occurrence where even the lion himself is a considerable sufferer by coming into collision with this plant. So great is the development of the thorny character in this region that Grisebach connects it particularly with desert exposure and scarcity of vegetation. Nor are thorny plants by any means confined to such regions—on our own heaths the gorse is a familiar plant, and one sufficiently formidable to passers-by; while other spiny Leguminosæ, as the wrest-harrow (*Ononis spinosa*), are not infrequent by the wayside. A further peculiarity may be noted in connection with these plants: often the thorns do not occur above the point which is assailable by the animal in its search for food; while, when the shoot has outlived its period of succulent condition, and its tissues have become hard and dry, the thorns do not persist, being much more numerous when the part is young.

Nor is this spiny habit confined to shrubs or trees. The cactuses, which are so remarkable a feature of the vegetation of America, are equally well protected. Their surfaces show great variety of development in this particular: some have small groups of thick rigid spines, others long flexible needles of intense sharpness, penetrating easily the skin of the assailant, and almost impossible to extract.

More formidable defences even than thorns or prickles are found in the varieties of stinging hairs borne so plentifully on the leaves of many plants. These are represented in England by the two species of stinging nettle, which are, as every one knows, capable of producing considerable discomfort to the unwary person who handles them. These are, however, not worth mentioning by the side of many of their tropical relations. The structure of the hair in all these is similar: a mass of cells forms a kind of swollen cushion below; on this is seated the long tapering hair, which ends in a somewhat recurved point or hook. The walls of the upper part of the hair are very strongly silicified, and are, consequently, easily ruptured. Lower down there is but little silica. When touched or rubbed by the hand, the pressure drives the hair downward; at the same time the brittle hook penetrates the skin and breaks off. The downward pressure forces out from the broken hair a fluid of intensely acrid nature, which, on entering the wound made by the point, sets up more or less severe inflammation. This fluid is generally conjectured to be formic acid—a

view based on the fact that this acid can be obtained from the nettle plant by suitable means.

While the English representatives of this group of plants are sufficiently formidable to careless intruders, some of their connections in other parts of the globe are distinctly dangerous. A traveller in Australia describes a specimen of *Urtica gigas* in the following terms:—"A specimen seen by Sir W. McArthur, still in full vigour, rises from its base by a series of buttresses of singularly regular outline, gradually tapering, without a branch, to a height of 120 to 140 feet. The trunk then divides into a regularly-formed, wide-spreading head, which excites admiration from its extraordinary size. But the ordinary elevation of this tree is 25 to 50 feet, with a circumference of 12 to 20 feet. The leaves, when young and in vigorous growth, attain a breadth of 12 to 15 inches, and are of a beautiful dark-green colour. As may be expected, the poisonous fluid secreted from the foliage is very powerful, particularly in the younger leaves, and their sting is exceedingly virulent, producing great suffering, not unattended with danger. It is found in the northern part of New South Wales, and is a great impediment to the traveller." An Indian species (*Urtica* or *Laportea crenulata*) is equally obnoxious. It has rather large leaves, round which numerous small stinging hairs are placed. At certain seasons it emits when bruised so irritating an aroma as to cause a copious flow of saliva and mucus from the nose and eyes for many hours, while violent fevers have been caused by the fluid poured out from its ruptured hairs. *Urtica urentissima*, a Timor species, which is known to the natives by the significant appellation of "devil's leaf," has been known to produce effects so violent as to last twelve months, and has in some cases even caused death. *Malpighia urens* bears on its leaves hairs $1\frac{1}{2}$ inch long, which are pressed flat along the surface. These act very similarly to those of Urtica.

The Loaseæ, or Chili nettles, exhibit similar defences, their power of stinging being very severe.

Other plants are protected also by hairs, which play rather a mechanical than a chemical part. Such are various species of Deutzia, particularly *D. scabra*, which bears on its leaves numerous star-shaped hairs whose walls are permeated with silica.

Besides these defences, which are chiefly mechanical, though in the case of the nettle a secretion acting chemically plays an important part in their behaviour, many plants are protected by chemical means alone. This is seen chiefly, though by no means exclusively, in the case of flowers and fruit. The plant secretes in different parts, or it may be throughout its system, a juice which may be poisonous, or acrid, or harmless in effect, but very unpleasant to its assailant. Thus very many of the Solanaceous plants have poisonous fruit, as *Atropa Belladonna*, and some species of Solanum. The whole plant is charged with juice of great pungency in many of the Ranunculaceæ, *R. sceleratus* causing sores if allowed to come into contact with a delicate mucous membrane such as that of the mouth. Parts of the Aconite (*A. Napellus*) are intensely poisonous, while the seeds of *Strychnos Nux-vomica* yield the well-known drug strychnine. Others have a latex or juice which is intensely bitter and unpleasant to the taste, as the different species of spurge (Euphorbia), the dandelion, the wild lettuce, different species of poppy, and many others. An acrid juice is to be met with in many Cruciferæ, as the mustard and the radish. The aromatic Umbelliferæ, also, are protected in this way from many of their enemies, the peculiar flavour which they possess being very unpalatable to many birds which are attracted by their fruits. Other plants pour out resinous and other sticky secretions which serve the same purpose. Some others are protected by the possession of a very fœtid odour, much resembling putrefying animal matter, though this has probably been developed to attract the carrion-loving flies which secure cross-fertilisation of the plants. Such are *Arum Dracunculus* and Stapelia, a genus of Asclepiadaceæ.

A very different kind of defence against intruders is found in a Sumatran parasite, *Hydriophytum formicarum*. This plant, instead of developing special weapons of its own, attracts to itself a colony of ants whose sting is very severe. These resent very effectually the attacks of animals inimical to the plant. It is described as parasitic on trees in the form of a large irregular tuber, fastening itself to them by fibrous roots, and throwing out several branches above. The tuber is generally inhabited by ants, and is hollowed out by them into numerous winding passages, which frequently extend a good way along the branches also, giving them the appearance of being fistular. A similar arrangement is found in *Acacia sphærocephala*, but a more elaborate one, as the plant not only serves as a habitation for the ants, but develops certain organs to attract them to it. The stem and branches are furnished with very large thorns, which are set along them in pairs. The thorns are enormously swollen at their bases, which are hollow, and in these swellings the nests of the ants are found, the magnitude of the enlargement being no doubt caused by the irritation of the insects. At the base of each pair of thorns, about midway between the two, is found a large nectar-secreting gland, which is very active. The leaves of the plant are pinnate, and on the leaflets are numerous small pear-shaped glands, consisting of delicate masses of cells containing an oily secretion. *Cecropia* is also protected in the same way; its stem is hollow, and contains the nests of the ants. As in the case of the Acacia, glandular structures are present, which attract the ants and afford them food. Schomburgk describes a plant belonging to the order Polygonaceæ (*Triplaris Schomburgkiana*), a native of Guiana, as having its trunk and branches hollow between the nodes, and serving as the habitation of venomous ants. He also mentions an orchis (*Schomburgkia tibicinis*), which, he says, has pseudo-bulbs arising from creeping root-stocks. These have a small hole at their base, and ants and other insects construct their nests therein.

Turning more especially to the reproductive organs of plants, we find them attractive to intruders, not only on account of their own palatability or succulence, but as providing two especial delicacies much sought after by the insect world—honey or nectar, and pollen. The object of the secretion of the former is to secure the due transference of the latter from the stamen of one flower to the pistil of another, and this is effected in most cases by some particular insect. The invasion of others would hence lead to loss of honey or pollen, or both, without securing the end aimed at. It is natural, therefore, to expect to find many contrivances to secure the secretion to the appropriate insect, and an almost infinite variety is found, some mechanical, others chemical, others partaking of the nature of both. The enemies most guarded against are those insects which we have seen in some other plants especially courted—ants. In assailing the plant they must usually ascend the stem from the ground, and many and various are the pitfalls placed in their way. In the teasle, the leaves, arranged in pairs along the stem, have their bases attached to it and to one another, forming deep cups, which are filled with water, thus presenting an obstacle to their ascent. The leaves of the pine-apple are arranged to bring about the same result. Some plants are surrounded in their growth by water, as many of the Polygonaceæ. In *P. amphibium*, which grows sometimes in water, and sometimes on land, and has two characteristic forms accordingly, the land form has developed round the flower-stalks a number of sticky glands, while the water form has nothing of the sort. The two forms are protected from the ants, but by different means. *Silene*, the catchfly, and *Circea*, the enchanter's nightshade, also are examples of plants furnished with sticky glands. *Lactuca*, the wild lettuce, emits

a milky juice on being assailed by them. Other plants, as some varieties of the willow, have very slippery flower-stalks, which the ants cannot pass along. The forms of the flower, too, lend themselves to protective purposes: thus *Antirrhinum* and *Linaria* have a close-shutting corolla, which they cannot enter; *Cobœa* is furnished with free hairs growing on the corolla, which block the way to the nectar, and which are insurmountable by the insects Where such means are not found, in some cases a counter-attraction is provided to draw the unwelcome visitors to parts where their attentions will be harmless: thus *Impatiens* has honey-glands on the leaves which are said to stop the ants on their way to the flower.

Other insects than ants are also to be guarded against. Many flowers are capable of fertilisation by more than one species of insect, but others are especially adapted only to one kind. In these the form of the flower, while affording facilities for the proper insect to receive its pollen upon the proper region of its body, also presents obstacles to others which would be useless. The peculiar construction of the corolla in such cases serves as a protection to both nectar and pollen. This may be carried still further, access to the honey by other than the appropriate channel being hindered by chemical means. An instance of this is seen in the Alpine varieties of the Aconite, which are adapted for fertilisation by bees. Instead of the insect inserting its proboscis into the flower from the front, so as to make it pass the stamens and pistil, one bee (*Bombus mastrucatus*) bites a hole in the back of the hood formed by the sepals, and abstracts the honey. The white variety of the flower is unprotected against the theft, but the other, blue in colour, has a nauseous, bitter taste, and so is let alone.

Besides meeting the attacks of animals in these different ways, plants have to cope with other dangers, and require for these another system of defences, which are more associated with peculiarities of environment. They are assailed continually by varying conditions of climate and temperature, and have in many cases very curious modifications of structure and habit to correspond with these. A danger that threatens most plants, except in a few regions of the world, is that of having their pollen injured by rain. To meet this many varieties of form of corolla have been developed. Many have a long narrow tubular shape, the claws of the petals cohering together, while the free limbs can curve outwards in fine weather, but arch over the tube when wet. Others have a campanulate form, with the base of the bell upwards, so that rain falling on the flower cannot get near the stamens, but is shot off as by a roof. In others the stamens are covered over by development of another part of the flower, as in the Iris; the filament of the stamen, too, may be broad, and bear the anther on its under surface, as in the Naiadaceæ. It is rather curious that flowers that produce large quantities of pollen have not such defences against this danger as those which form but little, while the most complete adaptations are found in the cases of plants that inhabit damp climates.

Many flowers are defended by habit rather than structure. In wet weather they do not open their corollas at all, and not a few, even in fine weather, keep open for a very little while, only a few hours in many cases.

Besides rain, other meteorological conditions are fraught with danger. One of the most commonly occurring is frost; and allied to this is the loss of heat by radiation during the night. The power of resistance to these conditions varies very much, but in many whose constitution makes them peculiarly susceptible to damage thereby there has been developed the so-called power of sleep. The term is no doubt a misnomer, but it has been adopted and associated with certain well-defined movements which the leaves of the plants perform at the close and at the beginning of day. The movements differ very greatly with different plants, but they bring about such a position of the leaves as will protect the upper surface from radiation. Some of them are of a very complex nature, particularly those shown by certain of the Leguminosæ, which have pinnate leaves. It is in this natural order that the property of sleep is most prevalent, certain of the Oxalidaceæ and their allies coming next to them.

A similar mechanism protects very many plants from excess of sunlight, which is injurious to the chlorophyll. In bright sunshine the leaves assume a position which has been called "diurnal sleep." In it they present their edges and not their faces to the light. In other leaves the chlorophyll corpuscles themselves move, taking up a position on the lateral walls of the cells rather than on the front ones, or so placing themselves that their profile and not their surface is exposed to the sun. In some of the Algæ, as *Mesocarpus* and *Vaucheria*, this sensitiveness is seen.

Other protective devices may be seen by studying the adaptations of plants to their conditions of life. Thus the leaves of submerged plants are preserved from being broken by the currents of water by being minutely subdivided, so that they adapt themselves easily to the motion, and do not oppose a resistance. Desert plants are protected from drought by the development of a succulent habit. Aërial parts of plants, again, are protected in many cases from becoming moistened by water by a deposition in the cuticular layers of the epidermis of varying amounts of wax or resin.

THE ORIGIN OF OUR POTATO

THE year 1886, by its tercentenary associations, brings once before us the subject of the introduction of the potato into our islands, but brings it still with most of the connected questions unsolved.

How, and when, and whence it was brought was considered by Banks in 1808, and it was by him attention was drawn to a manuscript statement in 1693 by Dr. Southwold Smith, F.R.S., that his grandfather received it from Sir Walter Ralegh, and sent it to Ireland.

It was considered by Sabine in 1822, when he concluded a paper before the Royal Horticultural Society with the remark, "The introduction of the potato *into* Virginia is still involved in obscurity."

It has been considered by De Candolle in his "Géogr. Bot. Raisonée" in 1855, and more recently in his "Origin of Cultivated Plants" in 1882. It has also been considered by others. While of the old unanswered questions some are now regarded as of mere antiquarian interest, there are others to which greater importance is attached than there ever has been before.

Among the latter a fresh interest has been given by Mr. Baker's paper before the Linnean Society in January, 1884, to the old question, was it *S. tuberosum* that was introduced from Virginia? The suggestion he, in conjunction with Earl Cathcart, has thrown out, that to strengthen our cultivated potato against disease we should cross with some other species of tuber-bearing Solanum, makes it important we should clearly know what is the species we have been for 300 years cultivating. There are many other questions surrounding the consideration, some of which border on that fundamental question, What constitutes a species?

That simple but highly practical method of approaching the question, "What is our species?" the method of introducing supposed distinct wild species, and watching their changes from year to year in cultivation, has not yet been followed sufficiently long, nor with a sufficient number of such species to effect much more than establish well-founded hopes that by it there is much we may learn. At present the twenty (?) years' cultivation of *S. maglia* is the only experiment on which we can rely. What conclusions such experiments may eventually lead s to it is impossible to predict, but this is certain, that

proceeding by such a method on fact, and untrammelled by tradition, the results will be sure. Hitherto we have relied over much upon traditions and mis-called history. It has been assumed that our species is a Virginian species, and beyond that the question, till recently, has not been pushed.

It would be a fitting observance of the third centenary of the date that may be most reasonably fixed for the introduction from Virginia, if we could celebrate it, not by speeches and after-dinner toasts to the memory of Drake or of Ralegh, but by clearly laying down our lines of inquiry, for they have been very ill-defined.

It may be one useful part of the work to reconsider the traditions and inferred history of our potato—for there is no doubt that botanists, if not perhaps actually led astray, have at least been hampered and puzzled by them.

One of the commonest traditions repeated over and over again in histories, dictionaries, works of gardening and agriculture, is that Sir Walter Ralegh brought the potato from Virginia. The great error in this is that Ralegh never was in or near Virginia.

His patent for founding an English colony in the New World was granted March 25, 1585, and he parted with it on March 7, 1589. We have records of the various expeditions sent out at his cost to endeavour to establish and maintain a colony, with the dates of sailing and returning, the names of the captains, and other details. Ralegh's life all through the period is known, and his time is so fully accounted for that he could not have gone out even *incognito*. The traditions, therefore, that he brought both the potato and tobacco from Virginia, may be for ever laid at rest. Whether some of his returning colonists, or one of the returning ships that had been sent out with supplies, brought it, is another question. There is not even tradition to that effect, far less any statement in the contemporary history of any of the expeditions.

Gerard, however, in his "Herbal," 1597, at p. 781, describing the "Potatoes of Virginia," says: "I have received rootes hereof from Virginia, otherwise called Novembeya, which grow and prosper in my garden, as in their owne native countrie." The value of Gerard's picture and letterpress will be presently discussed, but the point here to notice is that he makes the statement that he did receive "rootes" (by which, of course, he means tubers) from Virginia. One of the names he mentions for the potato is "papus." The name "papus" also occurs in the first catalogue of plants growing in his garden in 1596, so that the "rootes" he had he received not later than early in that year. The exact date is perhaps unimportant, as there is no record of any expedition to Virginia after 1590 till 1606. The land named Virginia was first visited in 1584. The introduction is therefore limited to some time between 1584 and 1590. At a period when the study of plants was confined almost wholly to apothecaries, and when sea captains thought more of fighting a Spanish or Portuguese ship than of observing the natural products of a newly-discovered land, it was not expected that the account of a voyage should refer to roots brought home. The sea-lion that roared its presage of Sir Humphry Gilbert's death is of course carefully described as a marvel, but a root is too ordinary a thing for notice. Can we by any consistent inferences account for the introduction between 1584 and 1590?

That learned mathematician, Thomas Heriot, who went out in the expedition of 1585 and returned in 1586, wrote a report on the "commodities" of the then known area of Virginia. The Island of Roanoak contained the head-quarters, and we know from Lane's report that exploring expeditions had been sent to the south for 80 miles, to the north for 130 miles, and also to the north-west for 130 miles. But that was all that was known of Virginia till the time of James I. The second part of Heriot's report is "of such commodities as Virginia is knowen to yeeld for victuall and sustenance of man's life usually fed upon by the naturall inhabitants as well also as by us during the time of our abode; and first such as are sowed and husbanded." Under the sub heading "of roots" he says:—"Openauk are a kinde of root of round forme, some of the bignesse of walnuts, some farre bigger, which are found in *moist* and *marshy* grounds growing many together one by another in ropes as though fastened with a string. Being boiled or sodden, they are very good meat." In the third edition is added, "Monardes calleth these roots beads or paternostri of St. Helena" ("Monardes," parte 2, lib. 1, cap. 4). This report is dated February, 1587, seven months after his return to England. How far it was written from memory we have no means of knowing. But this should be noticed—that Lane says that when, after much discussion, the colonists decided on returning to England, their departure was so hurried that there were "left or thrown over, cards, books, and writings." Heriot nowhere speaks of writing or making notes on the spot.

It has been generally supposed that the root here described under the name "openauk" is the potato. It should not escape notice, however, that Gerard does not in any way allude to the name "openauk," and it is nowhere said that openauk was brought to England. The only mentioned habitat, "moist and marshy grounds," seems strange, but the usual answer (in conversation at least) to the objection is, if the openauk is not the potato, what is it? and Gerard's statement that he received potatoes from Virginia is taken to strengthen the supposition. The suggestion, however, has been made that it was the Jerusalem artichoke.[1] All that can be said is, there stands Heriot's description, and there stands Gerard's statement. To link the two together may be a fair assumption, but it remains a mere assumption. The omission by Gerard of any reference to the name "openauk" is against the supposition he received roots from Heriot personally. Gerard's use of the word "papus" calls for notice, but there is one point that should be referred to before quitting the openauk.

Heriot, who is said to have been Ralegh's mathematical tutor, describes himself in his report as "servant to Sir Walter Ralegh, a member of the colony, and then employed in discovery a full twelvemonths." If he brought potatoes with him, it would be by courtesy said Sir W. Ralegh introduced them. All the expeditions were his. But there is another tradition that Sir Francis Drake brought them. Different writers give different dates for this, which are evidently wrong. He could not have brought them in 1580 from the west coast of South America, because he arrived in November, after coming round by India and the Cape, and they would have sprouted on the voyage. That was the return from his famous circumnavigation. It could not have been 1585, because he left England, after four years ashore, in that year, and did not return till July 1586. If Heriot had anything to do with the introduction of the openauk, it is almost certain Drake brought it in 1586, for the circumstances of his return then were these. His knighthood, conferred upon him after months of deliberation for his great voyage round the world, firmly established his position, and he was intrusted with the command of a fleet to the Gulf of Mexico to harass the Spaniards. His instructions were to visit Ralegh's colony at Virginia on his way home. He called there on June 8, 1586, and found the colonists much distressed that the ship from England that it had been promised should be sent with supplies in the spring had not arrived. He stayed there many days, granted their request for a ship to be left with them, but, as many unexpected troubles arose, which are described by Lane,

[1] Asa Gray and Trumbull. *Amer. Journ. Sci. and Art*, xiii., May, 1877, p. 351.

they asked to be taken home, and this was done. Although at the last their departure was so hurried that writings, &c., were not embarked, it does not follow that there had not been opportunity during previous days to embark roots among other provisions. As openauk was among the products "husbanded," Heriot may have had a supply of unplanted roots ready to send home. If this were so, then two traditions would be reconciled. It would be Drake's ships, but Ralegh's colonists, that brought the potato, assuming the openauk to be the potato. This, however, is mere assumption. For the fact that Drake brought home the people there is abundant evidence, but respecting the roots there is not a word. If we wish, however, to account at all for Gerard's receiving potatoes from Virginia, this seems the only likely way in which he could have received them. The overdue relief ship that arrived a few days subsequent to the departure of the colony, and returned after a brief search, may possibly have brought them. All the other expeditions were later in the season than even Drake's return, while of the 349 colonists who went out in 1587 nothing was ever known after they were landed, though a relief expedition made search for them. Gerard distinctly says it was the "rootes" he received, and these could not, like seeds, be available at any time of the year.

It is commonly supposed that the introduction of the potato from Virginia is a duly authenticated historic fact. What forgotten manuscript records or letters there may be it is impossible to say, but at present our sole authority that it was brought thence is Gerard, while the linking of two traditions as here suggested is only assumption.

It has been already mentioned that while Gerard does not use the word openauk, he does give the name papus. Papus is not mentioned by Heriot as a word in use in Virginia; *how then did Gerard come to use it?*

From the travels of Pedro Cieza de Leon [1532–1550] we know that papas was the general name in Peru for an edible root in his time. The root was cultivated, and it was eaten boiled, or else dried in the sun and preserved, when it was called chuña. Acosta, whose travels in the same regions were later [1570–1587], gives almost identically the same information, as also does the native-born Garcilasso. They none of them, however, give any description of papas by which it is possible to identify the plant known by that name.

The two oldest known Continental botanists that give the name papas *in conjunction with a description* of the plant, are Clusius and Bauhin. In addition to descriptions, both give figures.

In his Φυτοπίναξ (1596) Bauhin describes a plant to which he gives the name *Solanum tuberosum*, but without any figure [Lib. v. Sec. 1, No. xix.]. In his "Matthiolus" (1598) he refers to it with a figure. Here he adds, "Vulgo Pappar Hispanorum vel Indorum dicitur." Clusius, in his "Rariorum Plant. Hist." (1601), describes a plant clearly the same, with a figure, under the name *Papas peruvanorum*. He says there is no doubt this was the plant Cieza de Leon refers to. The expression, "there is no doubt," is, however, somewhat removed from certainty. In 1620, Bauhin again, in his Πρόδρομος, in describing *Solanum tuberosum*, to which he here adds "esculentum," refers to Cieza; and again, in 1623, in his Πίναξ, mentions that this is the plant from which Acosta says chuña is made. Both Bauhin and Clusius give their descriptions as from growing plants.

It might be readily surmised that with such continuous traffic as there was between Spain and the domains she had conquered in South America, the roots so highly prized by the Indians should be carried home. To strengthen this surmise there is the tradition that gives the name of the first to introduce them, a "doctor" named Hieronymus Cardan. What is the history of the introduction into Spain is beside the present question. It is not improbable that with the sustained and frequent intercommunication between Spain and America it was repeatedly introduced. The case is by no means parallel to the question of the introduction into England from Virginia, in Gerard's time, when out of the six expeditions sent out only one made any explorations inland. The opportunities of introduction from Virginia were few. From South America to Spain they were numerous. It seems sufficiently established, both by Bauhin and Clusius, that a plant called papas was introduced and grown in botanical gardens, if not as a food; and that it came to be known as the papas of the Peruvians, of the Indians, and of the Spaniards, for Peruvanorum, Indorum, and Hispanorum seem indiscriminately used. That Clusius suggested its identity with the Arachnida of Theophrastus and other Greek writers is now of little interest. Bauhin was the first to recognise the plant as a Solanum, and his *tuberosum* occurs as No. XIX. in his list of Solanums, in his Φυτοπίναξ.

Though Cieza, Acosta, and Garcilasso drew what appears to have been a consistent distinction between papas (potato) and battatas (sweet potato), that distinction was not always maintained by later European writers. In a way it seems hopeless to endeavour to trace, the Portuguese and Spaniards now use different words for the potato: the former call it batata, and the latter papa. The confusion is more bewildering when the two names were used as synonyms. In botanical nomenclature we have lost papas, but retained battatas. The identity or not of *Battatas edulis* with the battata of the three Spanish travellers is wide of the present consideration. So also would be the question why the Quichan word *ascu* was not used by them. This, however, appears a safe rule—that when papas is mentioned by sixteenth-century writers it may be read as = Solanum (but not necessarily *tuberosum*); when battatas is mentioned it is requisite to see whether it is wrongly used as a synonym or intentionally used for a distinct plant. To the present day chuña is made in Peru from "papas," but apparently not from "battata."

Assuming the rule is a safe one that papas cannot be taken to mean battatas, but battatas may and often does mean papas, then such chronological data as the following are of interest as some indication of the spread of the plant among botanists in Europe. There may be others, but these are all the writer has been able to collect.

Dr. Scholtz had papas growing in his garden at Breslau (Vratislavia), 1587; Clusius received two tubers at Vienna from Hannonia, 1588; Bauhin, in his Πρόδρομος, mentions "iconem suis coloribus delineatam," 1590; Dr. Scholtz's "*Papas hispanorum*" is mentioned in a "Carmen" (pub. at Vratislavia), 1592; Bauhin refers to a "*Pappar hispanorum*" growing in his garden, of which he gives a description, 1596.

It was in this year (1596) that Gerard published the catalogue of plants growing in his garden in Holborn. There occur in it the two names *Papus orbiculatus* and *Papus hispanorum*. In this 1596 catalogue these names, as all the rest, occur without any English equivalent or any description or note. The catalogue is simply a list of names. The word batata does not occur, but Sisarum does. Another catalogue, commonly called a second edition, was published in 1599. The "Herbal" had been published in the meantime (1597). In this 1599 catalogue English names are added to the Latin. These occur: *Papus orbiculatus*, bastard potatoes; *Papus hispanorum*, Spanish potatoes. Batata does not occur. Sisarum does, but without any adjective (we cannot call these second names "specific," while the first were in no sense of the word "generic"), and the English name with this is skyrrits.

Although it would be a natural supposition that with the aid of the figures and descriptions in the "Herbal" it would be easy to identify the plants named in the cata-

logues, it is, on the contrary, a most perplexing puzzle. There are names introduced into the "Herbal" which do not occur in the catalogues, and names in the catalogues which do not occur in the "Herbal." That the "Herbal" of 1597 should not exactly agree with the catalogue of 1596, hardly excites surprise, but that the catalogue of 1599 should so differ from the "Herbal" is more than surprising, it is perplexing. If the explanation given by Mr. Daydon Jackson in his annotations to the catalogues is correct, then the *Papus hispanorum* of Gerard's garden was not the *Papus hispanorum* of Clusius and Bauhin; but this requires very close attention. It involves not only the question whether the *Papus hispanorum* of Dr. Scholtz was Solanum or Batatas, but also whether Bauhin is to be trusted as a cautious incorporator of statements. However highly Bauhin is to be esteemed as a botanist, he may have had a Pliny-like weakness for accepting anything he was told.

Mr. Daydon Jackson's explanation is this:—

"Herbal" of 1597		Catalogue of 1599
Battata virginiana and *pappus*—Potatoes of Virginia (p. 781) ...	=	*Papus orbiculatus*—Bastard potatoes.
Sisarum peruvianorum, sive *Batata hispanorum*—Potatus or Potatoes (p. 780)	=	*Papus hispanorum*—Spanish potatoes.
Sisarum (p. 871)	=	*Sisarum*—Skyrrits.

Supposing this to be the correct explanation, what are we to think of Gerard allowing his second catalogue to appear so like his first and so unlike his "Herbal"? One point is clear—he uses Papus, Batata, and Sisarum with such want of discrimination that no importance can be attached to his names. But it is strange he should, in both his catalogues, use Papus twice and Batata not at all, while in his "Herbal" he has both *Batata virginiana* and *Batata hispanorum*. According to accounts that have been handed down to us, the "Herbal" was based on Dr. Priest's translation of the Pemptades of Dodonæus, and the plates, with the exception of sixteen, were those that had been used to illustrate works by Jacobus Theodorus ("Tabernæmontanus") and L'Obel. It is said that Gerard so little understood his work that he put cuts in the wrong places, and made so many mistakes that Norton, the publisher and proprietor of the work, engaged L'Obel, who was then living in England, to correct the errors. Gerard resented this, and a quarrel with L'Obel followed. To what extent L'Obel's corrections went we have no record. He would at any rate, we may assume, prevent wrong names and cuts being printed with the letterpress. In the particular case of the three names under consideration, he was already well acquainted with the Sisarum or Batata (p. 780), as he had described it in his "Stirpium adversaria nova," written in conjunction with Pena, and published in London in 1570. He there gives the name Battades, Ignames—Anglicé, Potades. The cut in illustration used in the "Herbal" is that on p. 482 of Tabernæmontanus, where the name used is Sisarum. So that we can account for the names used in the "Herbal" thus:—Sisarum because it occurs in Tabernæmontanus; Peruvanorum is perhaps not to be accounted for. Batata because L'Obel had used it, and Hispanorum because it was first made known to Europe by the Spaniards, who brought it (most probably) originally from the West Indian Islands. Potatus, or potatoes, because that was the Anglicised form of Batata. It is possible that Gerard may have wished to introduce the word Papus, and that L'Obel cut it out.

With regard to the "potatoes of Virginia," Gerard would perhaps have his own way. He thought so much of his having grown some received from Virginia, that in his portrait he has a branch of them in his hand. With regard to the cut used in illustration, we know at present nothing. It is not taken from any other source, and it does not occur anywhere but in this 1597 edition. In the 1633 edition by Johnson the cut from Clusius is used, while Parkinson, in 1640, uses the cut copied from Bauhin. It is one of the sixteen new cuts, but where it was made we do not know, still less do we know whether it was made from a plant growing in his garden.

This last consideration, where the plant grew which is here figured, is closely connected with the question, How did he come by the name papus? In the text Gerard says, under "The Place":—"It groweth naturally in America, where it was first discovered, as reporteth C. Clusius, since which time I have received rootes hereof from Virginia." And then, under "The Names," he says:—"The Indians do call this root papus (meaning the rootes), by which name also the common potatoes are called in those Indian countries."

Although there is no known publication of Clusius so early as this from which Gerard could be quoting, yet, as he had been thrice in England, there is the probability that Gerard and he were acquainted. It is easy to see then that he might easily have had, indeed most likely would have, the South American name papus direct from Clusius.

But did he have anything else from him—a figure, a full description, a dried specimen, or even a tuber? Clusius had two as early as 1588, eight years before Gerard's first catalogue.

We have seen—

(*a*) That Cieza, Acosta, and Garcilasso speak of papas as a common name in the north-west portions of South America.

(β) That Clusius and Bauhin speak of the "papas of the Spaniards" growing in Europe (which Bauhin recognised to be a Solanum) as the same plant the three mention.

(γ) That it was known in several botanic gardens in Europe before the time of Gerard's first catalogue.

(δ) That Gerard in some way received information from or through Clusius that the plant was first discovered in America. America here evidently means South America.

With Clusius's information we can hardly doubt Gerard would also get the name papus. There is no trace of papus being a name used in North America. Fernandez de Soto, who travelled in Florida [Evora, 1557], mentions Batata, but not papas Benzoni, 1572.

It has been a puzzle to some botanists that papas should have such a wide geographical distribution as from Virginia to South America. The puzzle has partly arisen on the assumption that papus was a Virginian name. As there is not a fragment of evidence it ever was, and as we have seen a way in which Gerard might have had it, that part of the puzzle may perhaps be regarded as entirely withdrawn. There are a sufficient number left in connection with the potato to tax ingenuity.

Can we as easily dispose of the cut in the "Herbal"? Are we on the strength of that cut to continue to believe that *S. tuberosum* was wild within the area known as Virginia? For, though we get rid of the name papas we do not get rid of the wide distribution of *tuberosum* if the plant itself grew wild in Peru and in Virginia? Possibly experts in wood-cutting or collectors of old cuts may be able to say whether the cut is English or Dutch. Sequier says the cuts are brass ["Bibl. Bot.," 1740, pp. 72, 73]. Haller says: "In 'Bib. Bodl.' icones dicuntur æneæ esse: sed ligneæ sunt undique" [1771, tome i. p. 389]. Such a point as this could probably be cleared up definitely.

It seems anomalous that we should base our belief that *S. tuberosum* is a native of Virginia, on a single cut about which we know nothing more than this: that it appears in conjunction with the name potatoes of Virginia; that it was placed there by the direction of a man against whom the charge of deliberate misstatement in his so-called scientific work has never been cleared up; that for some reason it does not appear in the second edition

of the work. If it is charitably supposed that in this case Gerard did not intentionally mislead, still, if his reputation for being a muddler of other people's work is as well founded as it appears to be, he may have made some blunder. It is by no means a far-fetched assumption that his figure was from a Continental source, but that he thought it near enough to represent his Virginian "rootes." Apart from all other considerations it is difficult in at least one particular to reconcile the figure and the text. He speaks of "the temperature and vertues" of the potatoes, and says they are the same as of the common potatoes (*i.e.* his Sisarum). Unless this is a pure invention, many must have been eaten for this conclusion to have been arrived at. The size of the tubers is not greater than of fair-sized peas, and it would take the produce of half a hundred plants to furnish a single dish.

It is perhaps worth consideration whether an explanation of the catalogues different from that given by Mr. Daydon Jackson is possible. Is there any insuperable objection to their being read thus?—*Papus hispanorum* (the *P. h.* of Clusius, &c.), received from the Continent. *Papus orbiculatus* (for orbiculatus is a name of his own) received from Virginia. Sisarum—the "Skyrrits of Peru" (p. 780 "Herbal"), and that the common skyrrits were not mentioned in the catalogue. When he mentions papus in his "Herbal" he does not add either hispanorum or orbiculatus, and it might be he included both under papus there.

The important point however is whether that cut truly represents what he received from Virginia.

In close connection with this it cannot be overlooked that Bauhin gives openauk as a synonym. He also says, "Ex insula Verginea primum allata in Angliam, inde in Galliam aliasque regiones.' He had probably seen De Bry's edition of Heriot, and so obtained the name openauk. But his authority for the remainder of the sentence is not clear. Moreover it does not harmonise with his reference to Peru.

The question of the introduction of the potato is a very complex one, involving many other considerations besides those here referred to. The foregoing notes may, however, clear up the traditions about Ralegh and Drake, remove the difficulty about Gerard's use of the word papus, and perhaps lead to something more certain being known about that cut of Gerard's on which so much hangs.

The origin and change in the use of the *word* potato are subjects which, for their satisfactory elucidation, involve considerations that fall within the provinces of the philologist, the traveller, the bibliographer, the historian, the botanist, and, using the word in its wide sense, the geographer.

Potato is but the English way of pronouncing Batata.

But what is the word Batata? To what language does it belong? The first European knowledge of it appears to be traceable to Cuba, San Domingo, or some of the neighbouring isles at the time they were discovered by Columbus, 1492, &c. But then the sixteenth century writers on Peru also use it as if it were a common word there, and, if it were, it is at least interesting, if not strange, to find a word thus widely spread over and across districts where, it has been said, languages so vary with tribes that one cannot even understand another, though neighbouring, tribe. But first we have to consider is there any *contemporary* evidence that the West Indian natives did make use of a word which, when written by the Spaniards, appeared as *batata?* It would involve a special search among such materials as Navarette had at his disposal to decide that. Compilations are not to be trusted, and English versions are of no avail. What the actual word was, written by Columbus or his companions, is what is wanted. Then, if it were a true West Indian word, and introduced and known with some plant in Spain and Portugal in the early part of the sixteenth century, what is the probability that, at the middle of it, writers on Peru used it as a name that would be understood at home, even though not used by the South American natives. With regard to papas, it is distinctly stated by Acosta it was a native name in South America, but the writer does not know of any passage in which batata is said to be. It has been pointed out above how the mistake arose that papas has been considered a Virginian name, and it is possible batata may prove to be not a South American name at all. There is a Quichau word, Ascu, equivalent, apparently, to Papas, to which only Mr. Clements Markham among English writers seems to have drawn attention. At present, in English translations of travels in Peru, papas and batata appear often confounded.

Then in regard to our own use of the word batata, did we have it with roots through the Spaniards, or direct from the West Indies? The earliest use of the word does not yet seem to have been fully searched for. It may, however, be found earlier than in the list of literary quotations usually given. For example, it occurs in the account of Sir J. Hawkins's voyage, 1565: "Hennes, potatoes, and pines." The earliest description the writer has been able to trace of what the potato was is in the botanical work of 1570, published in London, Lobel's "Stirpium adversaria nova." A figure is given of the root of the Batata, and at the heading is "Anglice Potades."

But we might have had the word half a century before that through Spain, and the fact that Lobel introduces such a curiously-spelled form as the usual English one would imply it had been for some time in use among the common people. The mention of potatoes in the Hawkins voyage without any reference to what they were like would also imply that they were then as familiarly known as pines or hens.

The change of sounds from Batatas to Potades is curious. Why should the flat labial be changed to the sharp, and the sharp linguo dental be changed to the flat, in the same word? Again—the question is not so undignified as may at first appear—when was the form "taters" introduced? It has no doubt been a gradual change, but as a fact country people of the Victorian era no more think of using the form potatoes than those of the Elizabethan era did of using batata. In 1596 the form potaton is met with. In 1627 and 1676 potadoes, and in 1655 pottato. Batata itself, by the Spaniards, seems to have been spelled indifferently batata or battata.

Then there is another curious point. How has it come to pass that for the same plant the Spaniards of to-day retain papas, while the Portuguese use batata, for the plant we *now* call the potato.

In speaking of questions in connection with our having changed the use of the word potato from one plant to another it is an advantage for preventing confusion to refer to the two plants by their present botanical names, the *Batatas edulis*, which belongs to the convolvulus "order," and the *Solanum tuberosum* (perhaps including the supposed different species, *Maglia*), our common potato, which belongs to the nightshade "order." Of the two it was *Batatas edulis*, called then, long before Linnæus's binomial system, simply Battata, that seems to have been first known in Europe.

The first European knowledge of the plant *Solanum tuberosum* (or *Maglia*) was under the name papas, by which it was known till Caspar Bauhin recognised that it was a Solanum in 1596. The date 1596, if not exactly that of his knowledge, is the date of his first publishing it in his "Φυτοπινοξ."

Then as to dates of introduction.

As already said, the first European knowledge of Battata was in 1494 or 1495, that is, assuming that it was among the valuable products of the West Indies Columbus sent home to his patron sovereigns to demonstrate the value of his discoveries. It is mentioned he sent home vegetable products as well as gold. He sent spices,

dye-woods, fruits, and herbs, or intended to. In the history "Primer viage de Colon" (Navarette, cap. 1) is the passage,[1] "And besides there are trees of a thousand species, each having its particular fruit and all of marvellous flavour, so that I am in the greatest trouble in the world not to know them, for I am very certain they are each of great value. I shall bring some home *as specimens*, and also *some of the herbs*." Taking Washington Irving's inspection of Navarette's materials as reliable, Columbus knew the potato—the battata.

Then it is also probable, for here we have to deal with probability only, that the Solanum [under the name papas] was known in Spain soon after the conquest by Pizzaro [1527], when Cieza de Leon wrote [1532-50].

Both of these are at present but assumptions in respect to dates. The exact dates may perhaps be known in Spain. Possibly some people in England may know what is known, but the writer has been unable to trace anything more through the published second-hand statements.

We in England somehow knew the battata, pronounced and spelled potade or potate or potato, before the time of Hawkins's voyage, and before Shakespeare wrote his "Merry Wives of Windsor," where he uses the word. That Shakespeare's potato was the batata is clear from Gerard's reference to the confectioners using the battata as a basis for their sugar work (p. 781 of his "Herbal").

It was Gerard who called the papus (papus, as he chose to spell it, instead of papas) the Virginian potato, or bastard potato.

There in his work we have the word "batata," or patata, or potato, transferred to the papas, to Bauhin's *Solanum tuberosum esculentum*. Though Gerard does not use the word Solanum, his figure and description are sufficient identification. Somehow, though it does not seem possible to trace how, the word "potato" or "taters" has, as an English word, stuck to the *Solanum*. The "battata" has now dropped out of cultivation as an English root, and this no doubt has been the main cause of the transference of the word "battata" from the original battata to the "bastard" potato of Gerard—the Solanum.

The establishment of batata as a botanical name, its recognised description, and its admission into generic nomenclature have a curious history, but that is somewhat wide of the points more immediately under consideration.

The whole question is by no means yet worked out, but the above suggestions may draw attention to the subject.

W. S. M.

[1] Quoted second-hand through W. Irving's "Life of Columbus."

THE COLONIAL AND INDIAN EXHIBITION

THIS Exhibition was opened on Tuesday by Her Majesty in state. Science in one form or another will be prominent in nearly all of the sections. The Exhibition as a whole will be a geographical education in its widest sense. Not many can follow the example of Mr. Froude and Baron Hübner, and spend the best part of a year in visiting our scattered Empire. At South Kensington, in the course of a few days, however, we may learn even more of the products and people and geographical aspects of our colonies than we might do by an expensive voyage. Of course the main purpose of the Exhibition is to draw attention to the economical and commercial aspects of the colonies and India; but in doing so, necessarily the introduction of a considerable amount of science is involved. In nearly all the sections, for example, we find excellent large maps of the various colonies on the walls, besides the gigantic map of the world in hemispheres beside the gateway of Old London. Again, several of the colonies have sent specimens of their natives, and from India especially there is a considerable number of individuals of all ages representing the various races which form the heterogeneous population of that vast territory. So, from South Africa, we find Kaffirs, Hottentots, Zulus, and Bechuanas; Singhalese from Ceylon, and Malays from the Straits Settlements. In several of the sections, also, notably in India, do we find life-size models of natives; some of the finest of them are in the British Guiana Court, prepared by Mr. Im Thurn. Several of the colonies, again, have had large reliefs either of the whole or part of their territory prepared. Among the exhibits of the Indian Survey is a relief-map of the Peninsula from the Tibetan table-land to Cape Comorin, on the scale of thirty-four miles to an inch. One of the finest of these models is that of New Zealand by Dr. Julius von Haast, under whose care this Court is markedly scientific. He has brought over with him the skeletons of three large moas; numerous specimens of flora, fauna, and geology, and the exquisitely beautiful skeleton of a ribbon-fish prepared after the method of Prof. Parker of Dunedin. Maori ethnology is also amply illustrated, though we believe no actual live specimen has been imported. One of the finest conservatories of native plants in the Exhibition will be that attached to the New Zealand Court. But such conservatories will be a marked characteristic of this Exhibition, and will be found attached to the Courts of the Cape of Good Hope, Queensland, Natal, and other colonies. India, of course, has much to show of interest to science, besides its numerous groups of life-size models of natives taken from actual casts. Under the care of Dr. Watt the botany is very fully illustrated. The Geological Survey has sent a fine exhibit; while the Topographical Survey will have a Court to itself. In all the Australian colonies geology is a prominent feature, at least in its economic aspects, and so we may say of botany, at least so far as timber-trees are concerned. In the Australian and several other colonies, moreover, large collections of natural history have been arranged in cases, while of course the numerous game-trophies will interest the naturalist. The trophy of trophies, however, will be the great jungle scene prepared by Mr. Rowland Ward, into which it has been attempted to compress the whole of the fauna of India. It is a triumph of arrangement; and we may refer to it in detail in a future article. An almost equally striking scene is the landscape in the South Australian Court, representing an actual piece of country near Lake Alexandrina. Of course, as in the jungle scene, we have *multum-in-parvo*,—features which in reality are spread over a wide area compressed into a few square yards. But everything is on the scale of nature, and nothing introduced that is not actually met with. We have natives at various occupations, including a woman and child under a rude shelter of branches; kangaroos, wallabies, eagles, and other animals deftly posed; characteristic vegetation and rocks, with mountains away in the background. The model of Hong Kong and the neighbouring coast may also be mentioned. The West Indian Court contains much of interest. The woods of Honduras are conspicuous; many curious land and water products from Trinidad; and a fine collection of Columbian pictures and relics, and several fine paintings and photographs of West Indian scenery. Indeed, in all the sections, pictures, and especially photographs, are among the most conspicuous exhibits, and have much geographical value.

Of course this Exhibition is one of many-sided interest, and we have mentioned here only a few of the points that will attract those interested in science. Its educational value is evident, and we hope that teachers will take advantage of so exceptional an opportunity of giving their pupils a practical lesson in physical geography and its economical and "political" developments. Most of the colonies will publish special hand-books, and in several of them we are glad to know that science will hold a prominent place.

NOTES

We refer elsewhere to the opening of the Colonial and Indian Exhibition on Tuesday. It argues ill for the spirit in which this Show is to be conducted that the representatives of British science, on which the progress of England beyond the seas has so largely depended in the past and must depend in the future, were so conspicuous by their absence at the opening ceremony. Not even the President of the Royal Society was invited to be present, though tickets were liberally distributed to a large number whose prior claims we do not care to discuss.

Science was well represented by the President of the Royal Society at the Royal Academy dinner on Saturday. Prof. Stokes showed how in several ways science is capable of rendering service to art. The rules of perspective, he pointed out, involved clear geometrical conceptions; while a knowledge of chemistry and physics would keep the artist often from violating nature. Prof. Stokes illustrated the point by referring to the inverted rainbow picture, adduced as an example for a similar purpose in these pages some years ago. At the same time he admitted with justice that art was not without its uses to science. Especially useful was it, he pointed out, as a refreshing and invigorating change for the mind of the scientific student, apt to get clogged and dulled by too eager direction to one particular subject.

The Fifty-sixth Annual Meeting of the British Association will commence at Birmingham on Wednesday, September 1, 1886. The President-elect is Sir William Dawson, C.M.G., F.R.S., Principal of McGill College, Montreal, Canada. Vice-Presidents: The Right Hon. the Earl of Bradford, Lord-Lieutenant of Shropshire, the Right Hon. Lord Leigh, Lord-Lieutenant of Warwickshire, the Right Hon. Lord Norton, K.C.M.G., the Right Hon. Lord Wrottesley, Lord-Lieutenant of Staffordshire, the Right Rev. the Lord Bishop of Worcester, Thomas Martineau, Mayor of Birmingham, Prof. G. G. Stokes, Pres.R.S. (nominated by the Council), Prof. W. A. Tilden, F.R.S., Rev. A. R. Vardy, Rev. H. W. Watson, F.R.S. General Treasurer: Prof. A. W. Williamson, F.R.S., V.P.C.S., University College, London, W.C. General Secretaries: Capt. Douglas Galton, C.B., F.R.S., A. G. Vernon Harcourt, F.R.S. Secretary: Arthur T. Atchison. Local Secretaries for the Meeting at Birmingham: J. Barham Karslake, Rev. H. W. Crosskey, Charles J. Hart, Council House, Birmingham. Local Treasurer for the Meeting at Birmingham: J. D. Goodman. The Sections are the following:—A. Mathematical and Physical Science—President: Prof. G. H. Darwin, F.R.S.; Vice-Presidents: Donald MacAlister, M.D.; Rev. H. W. Watson, F.R.S.; Secretaries: R. E. Baynes (Recorder), R. T. Glazebrook, F.R.S., Prof. J. H. Poynting, W. N. Shaw. B. Chemical Science—President: William Crookes, F.R.S.; Vice-Presidents: Prof. Carnelly, W. H. Perkin, F.R.S.; Secretaries: Prof. P. Phillips Bedson (Recorder), H. B. Dixon, F.C.S., H. Forster Morley, D.Sc., F.C.S., W. W. J. Nicol, Ph.D., C. J. Woodward, B.Sc. C. Geology—President: Prof. T. G. Bonney, F.R.S.; Vice-Presidents: Prof. C. Lapworth, F.G.S., H. Woodward, LL.D., F.R.S., F.G.S.; Secretaries: W. Jerome Harrison, F.G.S., J. J. H. Teall, F.G.S., W. Topley, F.G.S. (Recorder), W. W. Watts, F.G.S. D. Biology—President: William Carruthers, F.R.S., F.L.S.; Vice-Presidents: Prof. E. A. Schäfer, F.R.S., M.R.C.S., P. L. Sclater, F.R.S., F.L.S., Sec.Z.S.; Secretaries: Prof. T. W. Bridge, Walter Heape (Recorder), Prof. W. Hillhouse, W. L. Sclater, F.Z.S., H. Marshall Ward. E. Geography—President: Major-General Sir F. J. Goldsmid, K.C.S.I., C.B., F.R.G.S.; Vice-Presidents: Major-General Sir Lewis Pelly, K.C.B., K.C.S.I., M.P., F.R.G.S., Capt. W. J. L. Wharton, R.N., F.R.G.S.; Secretaries: F. T. S. Houghton, J. S. Keltie, F.R.G.S., J. S. O'Halloran, F.R.G.S., E. G. Ravenstein, F.R.G.S. (Recorder). F. Economic Science and Statistics—President: John Biddulph Martin, F.S.S.; Vice-Presidents: G. W. Hastings, M.P., F.S.S., Sir R. Temple, Bart., G.C.S.I., M.P., F.R.G.S., F.S.S.; Secretaries: E. F. Barham, Rev. W. Cunningham (Recorder), Prof. Foxwell, F.S.S., J. F. Moss, F.R.G.S. G. Mechanical Science—President: Sir James N. Douglass, M.Inst.C.E.; Vice-Presidents: W. Anderson, M.Inst.C.E.; W. P. Marshall, M.Inst.C.E.; Secretaries: Conrad W. Cooke, J. Kenward, Assoc.Inst.C.E., E. Rigg (Recorder). H. Anthropology—President: Sir George Campbell, K.C.S.I., M.P.; Vice-Presidents: Prof. W. Boyd Dawkins, F.R.S., Lieut.-Col. H. H. Godwin-Austen, F.R.S.; Secretaries: G. W. Bloxam, F.L.S. (Recorder); J. G. Garson, M.D., M.A.I., Walter Hurst, B.Sc., R. Saundby, M.D. The first General Meeting will be held on Wednesday, September 1, at 8 p.m. precisely, when the Right Hon. Sir Lyon Playfair, K.C.B., M.P., F.R.SS.L. and E., will resign the chair, and Principal Sir William Dawson, C.M.G., F.R.S., President-elect, will assume the Presidency, and deliver an address. On Thursday evening, September 2, at 8 p.m., a *soirée*; on Friday evening, September 3, at 8.30 p.m., a discourse on "The Sense of Hearing," by Prof. William Rutherford, F.R.S.; on Monday evening, September 6, at 8.30 p.m., a discourse on "Soap Bubbles," by A. W. Rücker, F.R.S.; on Tuesday evening, September 7, at 8 p.m., a *soirée*; on Wednesday, September 8, the concluding General Meeting will be held at 2.30 p.m.

The first general meeting of the Congress of French scientific societies took place in the large hall of the Sorbonne on April 27 at noon. M. Bertrand, Director of the Archæological Museum of St. Germain was in the chair. For the first time a special section has been created for geography, of which M. Bouquet de la Grye is chairman. The section of sciences was presided over by M. Faye, and divided into several sub-sections. M. Lhoste presented a pointed cask, with the assistance of which he hopes to keep a balloon floating in the air for several days over the sea. M. Certes, President of the Zoological Society of France, explained the use of colouring matters for the histological and physiological exhibition of living animalcules. The meetings were concluded on Saturday, May 1, by an address by M. Goblet, the Minister of Public Instruction, in which he advocated the establishment of a secondary education from which Greek and Latin should be excluded, their place being filled by modern languages. A number of decorations were awarded to members of learned societies and academies. M. Berthelot was created "Grand Officier" of the Légion d'Honneur.

The Department of Modern Ethnography in the British Museum being now arranged, the work of arranging the prehistoric section is being taken in hand by Mr. Franks. The three rooms immediately at the head of the western staircase, near the entrance, are devoted to this purpose. The collection will contain the Christy and Museum collections, which will be incorporated with each other, and also the Greenwell collection from British Barrows. The central room of the three will contain palæolithic objects from England and the rest of the world. The finds in the caves of the Dordogne will form an important and interesting part of these. These caves were excavated by the late Mr. Christy at his own expense, and the results added to his collection. The pictures were, at his wish, sent to France. The room on the left of the entrance contains Neolithic objects, arranged under the Stone and Bronze Ages, the objects from the various countries being arranged within the periods. Here Canon Greenwell's remarkable collection from the British Barrows (which will be maintained intact) will find a place. The special value of this collection is that the place and manner of finding of each individual object is known and recorded, and every cir-

cumstance connected with the discovery of each is known. The Barrows, from which the collection was made, are found mostly in Yorkshire, although other places are also represented. In the same room will also be placed the implements used in working flint quarries in prehistoric times, and other objects found there; there will also be some curious implements from countries where the Stone Age still exists, as it does, in a certain measure, in Madeira, Syria, and Iceland. The room on the right will be given up to iron objects, and those of an age which may be called semi-prehistoric, such as the Roman times in Britain.

A SUPERFICIAL examination of the ethnographical galleries in the British Museum shows that the American section is overcrowded. On the left are the American antiquities, which are of the greatest interest, but which do not seem to belong properly to ethnography at all, while the objects on the left, belonging to modern America, and which are certainly ethnographical, are crowded into a space which is quite insufficient. As much has been done as possible to arrange the objects, and there is no confusion, but it is quite impossible to examine the cases properly when they contain so much. Ancient Mexico, Peru, and New Granada crowd modern South, North-West, and Arctic America into a very small space. It is obvious that an attempt should be made to remove the American antiquities to some more suitable place, and to give up the whole of the gallery to American ethnography proper.

AFRICA does not seem so well represented in the Collection as it might be for a country which has sent its missionaries and travellers into every corner of the land. Two or three small South Sea Islands occupy about as much space as the continent of Africa. The only district well represented is that of the Upper Nile, the collection of Lupton Bey being specially noteworthy, as giving one a fair idea of the manufacturing industries of the people of these parts. South Africa is moderately well represented, and in a less degree northern West Africa. East Africa, Central Africa, and southern West Africa are all relegated to a small case and very poorly represented. A spear from one tribe lies beside a pipe or a dagger from another tribe a thousand miles distant. And yet in this enormous region there are tribes singularly expert as blacksmiths, potters, &c. No African tribe produces more beautiful spears than the Wa-Vira, more horridly barbed than those of Nyassa, or more remarkable than those of Maryema or of Masai-land; and yet good collections of all these are undoubtedly in the country. Owing to this meagre display the collection is not of much value for purposes of comparison or to illustrate the relative advancement of the various tribes in arts and manufactures, and yet in this respect there is as much difference between the most degraded of the tribes and the most civilised as there is between the latter and ourselves. The arrangement also leaves much to be desired. Articles manufactured by tribes totally distinct in race, degree of civilisation, and religion are thrown indiscriminately together. Take, for instance, northern West Africa. There one finds the fetishes, idols, and rudely-worked articles of the degraded and barbarous tribes of the Lower Niger figuring amongst the artistic and advanced productions of the Mohammedan and polished tribes of the Central Sudan, and nothing to indicate that they are not the work of one people. In the East African section, again, you find Somali weapons beside those of the Bantu tribes further south, such as the Wa-gogo. Some objects do not appear to be correctly named. Thus the backbone of a shield divested of the hide which it was intended to support now figures as a bow, a string having been stretched from point to point. The map to illustrate Africa is scarcely worthy of the British Museum. The Congo Basin is strikingly shown by an utter blank.

FROM the Royal Gardens, Kew, we have received a cheap, carefully arranged, and highly useful guide to Museum No. III. at that establishment, which is devoted chiefly to specimens of timber and other large articles unsuited for exhibition in the glazed cases of the other museum. Another extremely useful publication is a Route Map of the Royal Botanic Garden and Arboretum on a scale quite large enough to enable any visitor to find his way. The various sections of the gardens are clearly laid down, and on the back is an index to the various entrances, museums, houses, the arboretum, &c., corresponding to the sections in the map indicated by figures and letters.

A MICROSCOPICAL SOCIETY has been started in Glasgow with Dr. Dallinger as first President; over fifty members have been enrolled.

THE volcano of Smeru in Java is stated to be in eruption.

WE have received the first number of *The Indian Engineer*, published by Messrs. Newman and Co., Limited, Calcutta. This is a new publication, the object being to provide a representative organ for all branches of the Indian engineering profession, and to make it a creditable representative of the great engineering and scientific services of the country. The leading article appropriately gives a history of Indian engineering journalism. We are told that the first publication of the kind was made by the Corps of the Madras Engineers in the form of a series of papers, to provide a record of the experience of their members for future reference. Messrs. Newman and Co., twenty-eight years ago, followed this first attempt by publishing a paper called *The Engineers' Journal and Railway and Public Works Chronicle*. Since then several different papers have been issued with varying success. *The Indian Engineer* is nicely got up and well printed, and, to judge by the first number, will prove to be an interesting journal, containing as it does many very good articles on general Indian engineering, civil and mechanical. We trust it will receive general support, and in time become an acknowledged organ of the profession in India.

WE are pleased to see from the current number of the *Agricultural Students' Gazette* that the authorities of the Royal Agricultural College, Cirencester, have provided greater facilities for teaching the increasingly important branch of agriculture, dairy farming. A new working dairy has been erected and fitted with appliances of the most improved kinds. We notice also that further substantial accommodation has been made for out-students. The *Gazette* contains a description of the new buildings and an account of the College live stock; the dairy herd contains specimens of nine breeds, and the specimen flock of fifteen different breeds. An article by Mr. J. M. Muir-McKenzie, on cultivation in the Western Ghâts, gives a description of the prevalent method of cultivation in this part of the Bombay Presidency, by means of wood ash and *râb*; this style of native agriculture entails the destruction of much jungle and denudation of the hills to the detriment of the low lands; it raises various difficulties between the natives and the forest and other officials, and any attempt to grasp its scientific and economic bearings is worth careful attention.

UNDER the title of "Malvern Field Hand-book and Naturalist's Calendar," Mr. G. E. Mackie, Assistant Master in Malvern College, has published a little volume that will be useful both to residents and visitors. The Hand-book was originally begun for the use of the boys of the Malvern College Field Club, but has been much enlarged.

MR. THOMAS WARDLE, of Leek, has been to India to examine the cultivation of the silkworm (*Bombyx mori*) there, and the methods still in use of reeling the silk. Although the reputation of Bengal silk has gone down greatly during the last twenty-five years, yet microscopical examination satisfied him that the fibre of the Indian silk was quite equal to that of Italian, and that improvement in the machinery and method of

reeling was all that was required. The length of thread, however, in each cocoon was very different, the Indian worm only spinning 150 metres, while the more highly-tended and selected Italian worm produced 650 metres. It is suggested that the Government should rear a limited quantity of cocoons, from which a careful selection of "seed" only shall be made, since much of the present inferior quality is traceable to want of discretion in the choice of breeding stock. A loss to the growers of 60 per cent. of their grubs through hot winds can be prevented by the use of mud huts instead of matted walls only. The profitableness of the business is shown by the fact that the zemindars have been able to exact the highest of all agricultural rents for land where the mulberry is grown for this purpose: more than twelve times the amount paid for land adjoining planted with rice. But they do not realise that such high rents are not practicable now silk is at only half its ordinary price.

Mr. Fortescue, the Superintendent of the Reading Room in the British Museum, has just produced a catalogue which is new, as far as the Museum is concerned, in plan, and which will prove of the utmost benefit to all students, men of science included. It is a catalogue of all the works acquired during the years 1880–85 in all modern languages except Oriental, Hungarian, and Sclavonic, arranged according to subjects. At present the alphabetical system is that employed in the Museum Catalogue, and therefore, unless the student knows, or can ascertain, the name of his author, the Library and its Catalogue are of no use to him. With Mr. Fortescue's Catalogue one can tell at a glance what books have been published during the past five years in any given subject, or branch of a subject, in Europe, America, or the British Colonies. The work contains about 1000 pages, with from 50,000 to 60,000 entries. An analysis of one or two headings will best show the value of the Catalogue. To take "Chemistry," under the sub-head "General" we find, first, all important text-books, then elementary works, both grouped under the different languages; then follow Agricultural, Analytical, Arithmetical, Bibliography, Examination Papers, Inorganic, Medical (with cross-references to Materia Medica and Pharmacy), and, finally, Organic, with about 400 entries in all. This, of course, does not exhaust the subject, for under such heads as Acids, Alkalies, Alkaloids, and so on, throughout the book, we have also the titles of chemical publications. The subject Electricity is a remarkable one for the number of entries under it. They fill ten pages in double columns, and about half refer to the electric light. It is curious to notice, too, that fifty telegraph codes were published in the five years included in the Catalogue; these do not, of course, include the innumerable private and cypher codes.

A United States digest of the Report of the British Commissioners on Technical Education by an eminent pioneer in the work has been issued as a Circular of Information by the Bureau of Education. In the writer's earlier days "apprenticeship was rapidly disappearing and home manufactures were giving place to large mills and factories, and yet the schools in which the young were to be specially fitted for their career in the new order of industries were in a large measure limited to the old in methods and principles"—and far too little has there been any alteration since! The British Commissioners' Report is reprinted and added on to the text of this Circular, but the latter is chiefly an account of the French, German, and Russian technical schools, to the latter of which the writer gives the palm of excellence. In these schools, however, a great deal more than teaching is done. In St. Petersburg material is handled in the most wholesale style, and in Moscow orders for specially difficult work are taken and executed. Valuable, however, as such trained ability may be where trained ability is scarce, it is not a solution of the problem before England and America, where the object is to teach every youth the principles which underlie his work. The average age of youths who enter such institutions is over seventeen, and the course extends over five or six years. The result of much of such training in the advanced manufacturing countries must naturally be, as in Germany already, an overflow of highly-trained polytechnic students seeking something above an intelligent mechanic's work. A specially complete set of schools for teaching the various trades at Chemnitz is described. In France the work of such schools in providing a substitute for the extinct apprenticeship system is so efficient that, it is said, "the effort to avoid teaching trades will not be very successful," and they are found already to revive drooping industries and to make new ones. A most important observation, if generally borne out, is that much of this technical work can be added to, not substituted for, ordinary school work.

We learn from *Naturen* that a committee has been formed at Christiania to promote the long-projected establishment of a zoological garden in the Norwegian capital. The plan suggested by the promoters of the scheme is wisely adapted to the special collection of North European and Arctic animals, such as the Polar bear, reindeer, elk, and the numerous other members of the Cervus family to be found in high latitudes, while no attempt will be made to introduce animal forms belonging to tropical faunas, whose susceptibility to cold makes it difficult to maintain them in health even in zoological stations lying far south of Norway.

We are sorry to learn that bad weather greatly interfered with the success of Herr Stejneger's explorations of the Behring Straits fauna and flora during his last summer's boating voyage. At the extremity of Komandor Bay he believes that he has identified the exact spot at which Behring and his unfortunate comrades were shipwrecked, and where he perished from the effects of exposure in the winter of 1741. Here Herr Stejneger found buried beneath the soil various relics of this memorable expedition, including a thin brass plate stamped with the Russian double eagle. The search for plants and insects was specially unsatisfactory, for the damp mildewed the few specimens collected, and ruined all the cases and herbaria, while it so thoroughly rusted every fragment of steel and iron that all the instruments intended for meteorological and other observations were made useless.

The additions to the Zoological Society's Gardens during the past week include two Military Macaws (*Ara militaris*), a Red and Yellow Macaw (*Ara chloroptera*) from South America, presented by Mr. C. Clifton, F.Z.S.; two Ring Doves (*Columba palumbus*), British, presented by Lord Arthur Russell, M.P., F.Z.S.; a Jay (*Garrulus glandarius*), British, presented by Mr. R. Humphries; two Spanish Terrapins (*Clemmys leprosa*) from Spain, a Spotted Salamander (*Salamandra maculosa*), a Fire-bellied Toad (*Bombinator igneus*), six Axolotls (*Siredon mexicanus*) from Mexico, a Green Lizard (*Lacerta viridis*), European, presented by Mr. Alban Doran, F.R.C.S.; twenty Palmated Newts (*Molge palmata*) from Epping Forest, presented by Mr. G. A. Boulenger, F.Z.S.; a Collection of Sea Anemones, from British Seas, presented by Mr. W. L. Sclater, F.Z.S.; two Ring-tailed Lemurs (*Lemur catta*) from Madagascar, an Asiatic Wild Ass (*Equus onager* ♂) from India, deposited; a Ludio Monkey (*Cercopithecus ludio*) from West Africa, three Red-crested Finches (*Coryphospingus cristatus*) from South America, two Rosy-faced Love-Birds (*Agapornis roseicollis*) from South Africa, a Shining Parrakeet (*Pyrrhulopsis splendens*) from Fiji Islands, a Vinaceous Amazon (*Chrysotis vinacea*), a —— Conure (*Conurus* ——) from Brazil, two Short-eared Owls (*Asio brachyotus*), a Magellanic Eagle Owl (*Bubo magellanica*), a Pudu Deer (*Pudu humilis* ♀) from Chili, purchased; a Hairy-eared

Rhinoceros (*Rhinoceros lasiotus* ♂) from India, two Punjaub Wild Sheep (*Ovis cycloceros*) from North-West India, received in exchange.

OUR ASTRONOMICAL COLUMN

THE INFLUENCE OF PHASE ON THE BRIGHTNESS OF THE MINOR PLANETS.—Dr. G. Muller gives an interesting discussion in the *Astronomische Nachrichten*, Nos. 2724-2725, of the variations in brightness of seven of the minor planets. The determinations of the magnitudes of these objects were made by means of a photometer, on Zollner's principle, attached either to the Steinheil telescope of the Potsdam Observatory, of aperture 135 mm. aperture, or to the Grubb equatorial of 207 mm. aperture. The result of these observations seems to show that there is a real connection between the phase of these planets and their apparent brightness, and that Lambert's law of phase brightness does not apply to them. Dr. Müller further divides the planets he has observed into two classes. In the first class, which embraces Vesta, Iris, Massilia, and Amphitrite, the changes in brightness are only perceptible as the planet approaches opposition; in the second, which contains Ceres, Pallas, and Irene, the changes in brightness seem to be co-extensive with the changes of phase. The planets of the first group thus correspond in their behaviour to the planet Mars, and Dr. Muller thinks we may fairly infer therefrom a similarity in their physical condition to that of the ruddy planet. The planets of the second class would appear, on the other hand, to give a light curve similar to that given by our moon, or rather perhaps by Mercury; it is therefore not improbable that they bear more resemblance in their physical constitution to that body.

COMET FABRY.—The following ephemeris by Dr. S. Oppenheim is taken from the *Astronomische Nachrichten*, No. 2722:—

For Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log *r*	Log Δ	Brightness
May 3	5 1 16	7 33·1 S.	9·9351	9·2358	381·4
5	6 16 8	22 59·4	9·9617	9·4446	195·2
11	7 3 53	30 30·4	9·9877	9·5698	97·3
15	7 34 43	34 18·8	0·0130	9·6758	53·2
19	7 55 56	36 29 6	0·0373	9·7632	31·8
23	8 11 35	37 53·6	0·0606	9·8364	20·4
27	8 23 52	38 53·2	0·0828	9·8992	13·8
31	8 34 0	39 39·2 S.	0·1041	9·9528	9·8

The brightness on 1885 December 1 is taken as unity.

BARNARD'S COMET.—The following ephemeris by Dr. H. Oppenheim (*Astr. Nachr.*, No. 2714) is in continuation of that given in NATURE for April 1, p. 518:—

Ephemeris for Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log *r*	Log Δ	Brightness
May 6	1 41 34	39 23·5 N.	9·6858	9·8894	155
10	1 50 59	36 42·5	9·7087	9·8125	199
14	2 8 29	31 42·6	9·7429	9·7266	253
18	2 35 41	23 16·9	9·7828	9·6374	318
22	3 13 3	10 16·3 N.	9·8242	9·5619	371
26	3 58 59	6 32·5 S.	9·8648	9·5291	359

The brightness on 1885 December 5 is taken as unity.

THE APPLICATION OF PHOTOGRAPHY TO ASTRONOMY.—In Appendix III. to the "Washington Observations for 1882," Prof. Harkness, U.S.N., commenting on the difficulty of preventing the solar rays from disturbing the adjustments of a meridian instrument employed in observing the sun, points out that photography seems to afford an escape from the difficulty. He suggests that a transit-circle might be so constructed that its eye-piece could be readily removed, and a sensitive photographic plate inserted just behind its wire system. Then with the eye-piece in position stars can be observed, and the instrumental constants determined in the usual way; while at noon a photographic plate can be inserted, and an instantaneous exposure will suffice to give an image of the sun with the transit and declination wires of the instrument imprinted upon it. The position of the sun's centre relatively to these wires having been measured, this, together with the instrumental constants, the circle-reading and the sidereal time of exposure will give an exact determination of the sun's right ascension and declination. As the instruments will be exposed to the sun's rays only for a few thousandths of a second, no disturbance of its constants can, Prof. Harkness thinks, arise from that cause; and the results, in his opinion, would probably be superior in accuracy to any hitherto obtained by the usual methods.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *MAY* 9-15

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 9

Sun rises, 4h. 20m.; souths, 11h. 56m. 16·3s.; sets, 19h. 33m.; decl. on meridian, 17° 25′ N.: Sidereal Time at Sunset, 10h. 43m.

Moon (at First Quarter on May 11) rises, 9h. 12m.; souths. 16h. 58m.; sets, 0h. 36m.*; decl. on meridian, 16° 37′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	3 46	10 19	16 52	5 51 N.
Venus	3 0	9 4	15 8	0 0
Mars	12 40	19 34	2 28*	9 52 N.
Jupiter	14 21	20 39	2 57*	2 50 N.
Saturn	7 1	15 13	23 25	22 50 N.

* Indicates that the setting is that of the following morning

Occultation of Star by the Moon (visible at Greenwich)

Meteor Showers

Amongst the secondary radiants active at this time are the following:—From Lynx, R.A. 123°, Decl. 40° N.; near δ Libræ, R.A. 223°, Decl. 10° S.; from Delphinus, R.A. 304°, Decl. 7° N.; near ζ Cygni, R.A. 320°, Decl. 18° N.; near κ Andromedæ, R.A. 354°, Decl. 41° N.

BIOLOGICAL NOTES

THE HYMENOPTERA OF THE HAWAIIAN ISLANDS.—In the *Proceedings* of the Literary and Scientific Society of Manchester (vol. xxv. pp. 123-183) is a valuable contribution on the Hymenopterous insect-fauna of the Hawaiian Islands, by the Rev. T. Blackburn, B.A., who resided there for many years, with a short introduction and annotations by Mr. P. Cameron. Eighty-four species are catalogued or described, but Mr. Blackburn says he has taken over 100. The greater part of the species appear to be strictly autochthonous. Of the *Anthophila* (or bees) there are 14 species (excluding the introduced honey-bee), and it is curious that 10 of these belong to 1 genus—*Prosopis*. Of the *Fossores* there are 35 species, and here again there is a paucity of genera, for 19 are included in *Odynerus* and 11 in *Crabro*. Of *Heterogyna* (ants) are only 10 species; and about 25 species of the various parasitic and hyper-parasitic groups. No indication of any of the phytophagous forms occurs in the paper. Before Mr. Blackburn went to the Hawaiian Islands the insect-fauna was almost unknown, so far as what may be termed the

more occult (and therefore the chief) portion of it. Most of what had hitherto been discovered resulted from the casual visits of entomologists (not always trained to the subject). In Coleoptera alone he discovered about 430 species, of which nearly four-fifths appear to be strictly endemic, which is certainly noteworthy in considering the fauna of an insular group of volcanic origin. The minority of more recent "introductions" look largely in the direction of Western North America, with a sprinkling of Polynesian or Australian forms. The Rev. Mr. Blackburn's Hawaiian discoveries in entomology have an important bearing on the selection of naturalists to accompany exploring and other expeditions. A trained observer knows where and how to look, even if in doubt as to what he may find, and is always rewarded by new discoveries. An untrained hand scampers over the country, and, with every desire to distinguish himself, comes back and complains of the barrenness of the land.

VEGETABLE PARASITES OF CODFISH.—Some years ago Prof. Farlow called attention to the presence of a red fungus which was destructive to the dried codfish of the American fisheries (NATURE, vol. xxiii. p. 543). Since then Dr. E. Bertherand has given an account of poisoning which had occurred among the French troops at Algiers, caused, it was believed, by eating dried codfish, which had a vermilion hue owing to the presence of a fungus described by M. Mégnin in the *Revue Mycologique* (vol. vi. p. 114) as *Coniothecium bertherandi*. Specimens of fish with the same colour were also met with at Bordeaux and Dieppe, these latter presumably from Newfoundland. It would appear probable that Mégnin's fungus is the same as that originally described by Farlow as *Clathrocystis roseo-persicina*, Cohn.[1] In addition to this species, however, Farlow has described another parasitic form on the cod, *Sarcina morrhuæ*, which name had to yield in priority to *S. litoralis* of Poulsen, found on mud near Copenhagen, and which has lately been recognised by Saccardo and Berlese as occurring on codfish from Algiers. These botanists seem to think the *Coniothecium bertherandi* identical with *Sarcina litoralis*, and this latter to be but a condition of *Beggiatoa roseo-persicina*; but although they are found in company Farlow sees no good reason to think they belong to the same species. It is curious the form should occur in regions so far apart as New England, Algiers, and salt-marsh mud in Denmark, and it suggests the idea that salt may be the means by which the disaster is spread. Still another species, called *Oidium morrhuæ* by Farlow, by forming small brown spots on the surface of the dried codfish injures its sale, and has been found not only in New England, but also at Algiers.—(W. G. Farlow, *Bull.* U.S. Fish Commission, i. p. 1, February 8, 1886.)

SUPERIMPOSED STAMENS.—Mr. Thomas Meehan suggests a new interpretation for the appearance of superimposed stamens. Stamens are by most, if not by all botanists, regarded as exogenous lateral outgrowths from a caulome, in which latter there has normally been an arrest in its axial development. Stamens, however, occasionally will spring from the inner base of petals, and Mr. Meehan would account for this by taking the petal as the analogue of a leaf on an elongated branch, and the stamen as the development of an axial bud to the petal. "Branching and articulated stamens are frequent in those families that have these organs springing as it were from an axial bud at the base of the petal, as in a diminution or suppressed secondary branch we might expect them to do." In illustration of this idea Mr. Meehan refers to the flowers of *Mahernia verticillata*, Cav., a well-known Byttneriaceous plant from the Cape of Good Hope. The genus is separated from Hermannia chiefly by a cup-shaped gland at the middle of the stamen. A comparison with the axial development of the inflorescence shows the stamen to be formed on precisely the same plan, Mr. Meehan thinks, as the biflowered peduncle. This latter is simply a diminutive branchlet; after forming one node the longitudinal development becomes nearly arrested, and there is a short pediceled flower, then the bud in the axil of the bracteolate leaflet pushes up and over this, giving rise to the longer-stalked flower. So in the development of the stamen, a bud arises in the axil of a petal, the common peduncle is represented by the filament, and the cup-like gland at the middle stands for the bracteole of the bipedicels. Here one of the flower-buds wholly disappears, the innermost becomes the upper part of the filament, the real node may be at the connective, and then the theoretical floral leaves proceed to form the anther. The incised bract is reduced to the fringed cup-like gland from which the stamen proper springs, and he concludes from a survey of the whole subject that in many cases superimposed stamens are the development of theoretical axial buds at the base of the petals, and not the result of an interposition of an extra whorl of leaves for which there seems no warrant in phyllotaxy. It will be seen that even on this explanation the true stamen is phyllomic; the fact that foliage leaves often have stipules ought not, in a consideration of this interesting subject, to be overlooked. Mr. Meehan's observations may throw some light on the herotaxy of the floral organs.—(*Proc. Acad. Nat. Sci.*, Philadelphia, 1886, p. 9).

[1] *Bacterium rubescens*, Lank.

STRUCTURE OF LINGULA PYRAMIDATA.—From a very important memoir on the structure of this species by Dr. H. G. Beyer, we condense the following. In 1870, when Mr. Dall was studying the species of Lingula, he separated those species which he found provided with raised fulcra for the attachment of certain muscles, forming a median septum or one or two divaricating septa on the other valve, and formed for them the genus Glottidia. All of the known species (four to six in number) are exclusively to be found in American waters, while not a single species of Lingula has been found to occur in America. While the true Lingulas are almost always attached to a fixed rock or stone, Glottidia attaches itself, if at all, only when adult, and usually to a very small pebble or bit of shell. As to the structure of the shell, the author confirms in great measure the observations of Gratiolet, but describes the cuticle as a thin homogeneous layer, and immediately beneath it, sometimes aggregated in clusters, sometimes arranged in linear series, and at other times again irregularly scattered, he found a series of little round bodies, staining with hæmatoxylin, homogeneous, and without nuclei; these are regarded as homologous if not analagous to the bodies occurring within the organic septa in the shell of the Testicardine Brachiopods. Immediately adjacent to the cuticle and this layer of bodies comes a broad layer of horny substance and internally a thin calcareous layer, and these horny and calcareous layers alternate with each other in a number varying with the age of the animal. Towards the periphery the cuticle and horny layer alone are found, and these join the supporting layer of the mantle margin. A very intimate structural relationship exists between the body-wall, the mantle, and the peduncle. It seems doubtful whether the structures described by Vogt, Owen, Hancock, and others as muscles are in reality muscular in character. All the true muscles are smooth muscle-fibres, but other so-called muscles seem to be rather mesenchymatous supporting substance, lacking contractility, but perhaps possessing elasticity. The author's observations on the vascular system confirm rather the views of Shipley, Schulgin, and Morse than those of Hancock, and no central propelling organ over the posterior slope of the stomach was on transverse sections found. The number and division of the nervous ganglia indicated by Hancock for Waldheimia seem to be the same in Lingula, though Hancock's views have lately been criticised by Van Bemmelen. Hancock's details as to the reproductive organs are in great measure confirmed. Three excellent plates of anatomical details accompany this memoir.—("Studies from the Biological Laboratory, Johns Hopkins University," vol. iii. No. 5, March 1886.)

THE CUCKOO.—In the note on the cuckoo in the Biological Notes of April 1 (p. 519, line 6 from bottom), *January* was inadvertently printed for *June*.

NOTE ON EARTHQUAKES IN CHINA[1]

I HAD prepared for presentation to the Seismological Society of Japan a tabulated account of earthquakes that have been recorded in Chinese annals for the past thirty-seven centuries, but it was destroyed by fire during a riot last winter, and with the paper were destroyed also the works from which the seismic facts were derived. Perhaps, however, some general remarks which those records suggest may not be devoid of value.

Nothing can be inferred anent the relative frequency and destructiveness of earthquakes in ancient and modern times from Chinese history; from the earliest recorded earthquakes of Mount Tai in Shantung 1831 B.C. to the commencement of the

[1] Communicated to the Seismological Society of Japan by D. J. Macgowan, M.D.

Han dynasty 200 B.C., only twelve are recorded; tradition and written archives noting those only that presented extraordinary features; a bald list merely mentioning a disturbance of the rivers of the I. and Lo Hanan, 1808 B.C.; Wei, Chin, and So in Shensi, 778 B.C.; the formation of long chasms in the loess, 345 and 206 B.C. From the Han period, notices of the phenomena of course increase, accompanied betimes with a few details relating mainly to loss of life, and the succour afforded to survivors. Geographically considered, earthquakes in China may be grouped as insular, littoral, and inland.

On the island of Formosa earthquakes are hardly less frequent than in Japan, while on Hainan they are comparatively of rare occurrence. These islands form a portion of the great volcanic chain that girdles the coast of Eastern Asia; the Chinese portion rises from the submarine plateau that overlooks the profound abyss of the Pacific Ocean.

Insular earthquakes affect the mainland but seldom, and to a slight extent, which is noteworthy from the proximity of Japan, the least stable portion of the earth's surface, which seemed inexplicable until Prof. Milne's statistics showed that a large majority of earthquakes in Japan originated beneath the Pacific.

The absence from Chinese and Korean annals of notices of earthquakes in that peninsula long inclined me to regard Korea as comparatively exempt from seismic action, and recently, I addressed Consul E. H. Parker, of H.B.M.'s service in that country, for information, who obtained from the prefect of Chemulpo a communication on the subject, the purport of which is, that earthquakes are so infrequent and harmless that records are not made of their occurrence. It is more than ten years since an earthquake was experienced in that kingdom, and on that occasion no one was injured, nor were buildings thrown down. No information is obtainable on the subject from Manchuria, where presumably earthquakes are uncommon: there is, however, a record of a volcanic eruption having occurred about a century ago in that portion of the empire.[1]

The only existing volcanic action on islands of this coast is on the north of Formosa, near Keelung, where three solfataras are in ceaseless ebullition, affording large supplies of sulphur, and emitting during earthquakes so much hydro-sulphuric gas as to occasion a degree of *malaise* to the residents, and to discolour the white paint of ships.[2]

Facts respecting Formosan earthquakes are so scanty that the following from a Chinese writer is worth citing. It relates to an earthquake that occurred in Northern Formosa in the fifth month of 1693. "During that month the earth shook without cessation. A tract of country in which three villages were situated caved in; the inhabitants, however, had time to escape." Three years after that submergence, the narrator, a mandarin, who was on his way to procure sulphur from the solfatara "could see in a lakelet, where the water was shallow, tops of bamboos and other trees of those villages. While near the solfatara he heard for a day and night noises that resembled a cataract precipitated from a lofty cliff; the sound seemed to be near and all about, but no evidence of the cause of the noise was discoverable When, however, he arrived at the solfatara the mystery was explained, he there heard the same sounds like a rushing of subterranean waters."

Another active volcano is named in a Chinese account of Formosa. It is in Têngshan district in the southern portion of the island at Red Hill, near the Tanshin Creek, on a plateau. Probably it has not been in open action since Formosa was opened to trade, as it does not appear to be known to foreigners.

Formosan seismic action occasionally causes tremors to be felt on the mainland, which is due to the ordinary direction of earthquakes on that island, which are generally from south to north or the reverse. The Liuchiuan group is the centre of seismic force that does not appear to extend beyond those islands.

Submarine disturbances not unfrequently attend the insular earthquakes; the sea sometimes rises on the Formosan coast sixteen feet above the usual height. Independently of the terrene commotions of Formosa, its adjacent waters appear to be subject to submarine agitations occasioning what records of the mainland style "third" or supplementary tides; but these are of rare occurrence. The "tide-rips" that have attracted the attention of hydrographers are notable phenomena, but the following, from a local gazetteer, seems to indicate the existence of phenomena that cannot be referred to tidal action:—"Peculiar noises of the sea are sometimes heard which are commonly regarded as indicative of change of weather, sounds from the north foreboding rain, those from the south being followed by wind. Hissing noises are heard, at times they are low, at others loud; when low, they resemble the beating of a drum or the dropping of beans on that instrument: now, the sounds are near; anon, they are distant; stopping suddenly or continuing for hours. When the noise is loud, it is more noisy than the voices of a hundred thousand men, and the sea bubbles up: in very protracted cases the noises continue day and night for half a month; and when of short continuance the sound lasts three or four days. Coast landers err in supposing that these noises have connection with the weather. They are absent during rains and in drought, in winds and in calms. . . During the sounds, the sea is agitated by fearful billows and furious waves." If that extraordinary seething and roaring of the ocean were synchronous with earthquakes, the fact could not have escaped observation: indubitably that graphic description applies to submarine volcanic action; to which the submarine plateau of eastern Asia is subject, and to which also I attribute the supplementary tides of the adjacent coast. Some thirty years ago an island was thrown up by a submarine volcano on the south of Formosa; the pumice which is cast on the northern shores of that island is evidently a submarine production.[1]

As proximity to the belt of volcanic islands seldom disturbs the mainland of the northern littoral, so the adjacent coast of Southern China and Annam enjoy like exemption from insular throes: Chehkiang and Fuhkien are sometimes slightly visited by Formosan shocks, and even the Canton coast slightly, but Philippine earthquakes never affect Annam.

Earthquakes on the coast of China are frequent, but slight and harmless. Their harmlessness is evinced by the tall slender pagodas that adorn the hills and valleys, and they are generally very limited in area, with great diversity of direction, but a majority being from south-west to north-east.

The southern provinces of China, and yet more Indo-China, appear to be comparatively exempt from earth throes, which, however, may be due to lack of information from those regions, but there is evidently no seismic zone in tropical or sub-tropical eastern Asia such as exists in our mid-latitudes.

The tremors that are experienced in Chehkiang, Kiangsu, and coterminous regions to the west, are sometimes followed by the appearance on the ground of substances that in Chinese books are styled "white hairs." When I first called attention to records of that kind that are found in local gazetteers, I suggested that they might be crystals precipitated by gaseous emissions, such as were once reported as occurring after an earthquake in the south-west of the United States; from later descriptions of these "horsetail-like" substances I incline to the opinion that they are organic, perhaps mycillium.

In the summer of 1878 the vernacular press gave an account of the occurrence of the phenomena at Wusoh, a city on the grand canal, thirty miles north of Suchau. "At noon, June 12th of that year, shocks of an earthquake were experienced, which lasted several minutes (*Sin.* 'for the space of time taken in swallowing half a bowl of rice'); the motion was so great that sitting or standing was difficult, but no harm was done. Two days later at night there was a severer shock, after which, within and without the walls of the city, white hairs resembling a silvery beard, about three inches in length, were found, which boys pulled out of the ground, gathering handfulls in a short space of time." My list of Chinese earthquakes for the past two thousand years having been destroyed by fire I am unable to indicate the regions in which earthquakes were followed by the emission of "hairs," but my impression is that all, or nearly all, are alluvial valleys.

The chief foci of inland earthquakes are Yunnan, Szechuan, Shensi and Kansuh—and less frequently Shansi, Chihli, Shantung, and the central provinces, where they are more violent than in other portions of the empire, and frequently present continuous or protracted action, for example:—

A series of earthquakes occurred at Taiyuan, the capital of Shansi, in 1882, followed by shocks at brief intervals for a year. An earlier series occurred in the province of Chihli; the district

[1] Perhaps the following may be explained as a result of volcanic action far distant from Peking. In the month of June, 1465, during a gust of wind at the capital a sound was heard as of hail falling on the ground, when pellets the size of cherries were picked up. On breaking them open they emitted a sulphurous odour. The writer says he could not have regarded such a phenomenon as credible had he not himself witnessed it.

[2] "Head-dizziness" is said to be an occasional accompaniment of earthquakes on the mainland Slight shocks that occurred at Weichang-November 3, 1885, are described in the *Shen-pau* as exhibiting that phenomenon.

[1] For accounts of the volcanic region of Northern Formosa see Taintor's "Imperial Maritime Customs Report, 1865," and Hancock, 1881.

city Chiichow suffered most, not a house remained standing, many lives were destroyed; frequent shocks occurred for a year after. The province of Szechuan is also liable to continuance of seismic throes, one of these commenced in the fourth month, 1462, and continued eleven months—there were in all 375 shocks.

In the loess formation of Northern China (discovered and described by Baron Richthofen) the land is not unfrequently riven by earthquakes forming long narrow chasms of unknown depth that gradually disappear on account of the vertical cleavage and unstratified nature of loess.

In the first decade of the fourth month, 1828, an earthquake caused a fissure over three miles in length, twenty to thirty feet broad, from which a vapour issued that proved fatal to many: people, animals, houses, and tombs were ingulfed. About two months later, during heavy rain, the chasm gradually filled up.

The chief earthquake region of China lies in a great seismic zone, which extends from near the gulf of Chihli to the shores of the Caspian—including Turkestan and the Aralo-Caspian depression. In Eastern Turkestan they present a periodic character (five per annum with remarkable regularity). Yet there are few portions of the world so far removed from active volcanoes. Recent Russian exploration has discovered that the supposed Tienshan volcano is merely a solfatara, or an ignited coal-field.

Observations of officers appointed by the Emperor Chienlung to examine the newly subjugated territory in reference to these "firefields," are several. They say: "Three days travel to the east of Okishu and to the south of the hill at Palikeh there are several firefields. The ground is of a red colour, and a number of variegated stones are piled upon each other in the neighbourhood; from the middle of which flames upward of a foot in height are emitted: they are alternately extinguished and lighted up, while the smell is so strong as to render a near approach to the place impossible. For a distance of about 100 *li* not a blade of grass, not an inch of wood, nor a drop of water can be seen. From the peculiar smell of the fire thus raised, it is imagined that the soil must be strongly impregnated with sulphur."

The same work represents earthquakes as so common in Eastern Turkestan and the desert, that to the inhabitants "they are not considered strong; four or five occur every year; even when violent, they merely cause the doors and windows to rattle, but on account of the firm and adherent character of the soil, and thick walls and light roofs in common use, the houses are never thrown down."

A recent English traveller[1] makes a similar statement respecting Mid-Asian earthquakes generally. At Tashkend they generally average five in a year, but so slight, as not to be noticed by anybody. In that part of the world earthquakes appear to be most frequent at the close season. In the western portion of the seismic zone, they are of greatest frequency and violence in mountain regions.

Anent the opinion of M. Perrey, that a maximum of earthquakes is coincident with the moon's perigee, I submit the following statistical fragment that escaped the loss referred to: it is partially confirmatory of Prof. Milne's observations, that cold weather furnishes the maximum of frequency.

Lists of 738 continental shocks:—

1st month	65	5th month	46	9th month	56
2nd ,,	82	6th ,,	63	10th ,,	43
3rd ,,	72	7th ,,	70	11th ,,	65
4th ,,	49	8th ,,	70	12th ,,	88

(The first day of the first month occurs about February 6th, or at the new moon which falls nearest to the point when the sun is in the fifteenth degree of Aquarius.) In their seismic records the Chinese seldom designate the day of the month (moon) when earthquakes occur. Yet a considerable number may be found. Seventy-two cases show twice as many in the first and second as in the third and fourth quarters of the moon's phrases: forty-eight in the former period, and twenty-four in the latter; of that number fifteen occurred at the syzygies. The 6th day shows the largest number, twelve. None took place on the 2nd, 5th, 13th and 14th; one occurred on each of the following, 4th, 7th, 17th, 20th, 22nd, 23rd, 24th, 28th, 29th. Hours are rarely given; so far as they go, they show that a large majority are nocturnal.

[1] Lansdell's "Russian Central Asia," 1885.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The following list of lectures and classes in Natural Science has been arranged for the summer term:—

Physics.—In the Clarendon Laboratory Prof. Clifton lectures on Instruments and Methods employed in the Study of Optics. Practical instruction in Physics is given by the Professor and by Messrs. J. Walker and A. L. Selby. At Christ Church, Mr. Baynes lectures on Electro-Kinematics and Dynamics, and has a class for practical instruction in Electric and Magnetic Measurements. At Balliol Mr. Dixon lectures on Elementary Electricity and Magnetism. At Trinity the new Millard Laboratory will be opened for instruction in Mechanical and Electrical Engineering under Mr. Frederick Smith.

Chemistry.—In the Chemical Department of the University Museum Dr. Odling lectures on Some Special Points in Organic Chemistry. Mr. Fisher and Dr. Watts continue their courses on Inorganic and Organic Chemistry respectively. Mr. W. R. Dunstan lectures on Organic and Pharmaceutical Chemistry. Practical instruction is given in the laboratories by Messrs. Fisher, Watts, Baker, and Marsh. At Christ Church Mr. Vernon Harcourt has a class for Quantitative Analysis, and Mr. Dixon for Gas Analysis.

Animal Morphology.—In the Morphological Department Prof. Westwood lectures on the Haustellated Orders of Winged Arthropodous Animals. Prof. Moseley lectures on the Mammalia, Mr. Baldwin Spencer on Embryology, and Mr. J. B. Thompson on the Osteology, Distribution, and Odontography of Birds and Mammals. Practical instruction is given by Prof. Moseley and by Messrs. Robertson and Spencer. In Human Anatomy Mr. A. Thomson lectures on the Vascular and Respiratory Systems, and gives demonstrations on Topographical Anatomy. Daily instruction is also given in Practical Anatomy.

Physiology.—In the Physiological Department Prof. Burdon Sanderson lectures on the Chemical Processes of the Animal Body, and on Elementary Physiology. Mr. Dixey lectures on Histological Methods. Practical instruction is given daily.

Botany.—At the Botanic Garden Prof. Balfour lectures and gives practical instruction in Vegetable Morphology and Physiology. Prof. Gilbert gives four lectures on Rural Economy.

Anthropology.—Dr. Tylor lectures on the Origins of Civilisation.

Geology.—Prof. Prestwich lectures on the Secondary and Tertiary Series as illustrated by the geology of the neighbourhood of Oxford. Each lecture is followed by a geological excursion.

CAMBRIDGE.—The Special Board for Biology and Geology have recommended the following grants from the Worts Fund:

(1) 50*l.* to Mr. W. Bateson, of St. John's College, to assist him in investigations into the fauna of lakes in the neighbourhood of the Sea of Aral in 1886, and an additional 50*l.* if he continues his investigations into the summer of 1887. Mr. Bateson's investigations into the development of Balanoglossus in the Southern United States have, it is well known, been of great value.

(2) 60*l.* to Mr. A. C. Seward, of St. John's College, to assist him in studying and collecting fossil plants in Belgium and France.

(3) 35*l.* to Mr. Hans Gadow, of King's College, to assist him in exploring the ossiferous caves of Portugal, which he has already partly explored during two former visits. Prof. Boyd Dawkins strongly recommends the continuance of these explorations.

(4) 25*l.* to Mr. C. Potter, of Peterhouse, to assist him in elucidating the life-history of the alga parasitic on the water-tortoise in Portugal.

In the list of lectures issued by the Board of Physics and Chemistry for the present term we note that Dr. Ruhemann, assistant to the Jacksonian Professor, will lecture on Gas Analysis, and also on the Aromatic Bodies. The other chemical courses repeat the usual advanced and elementary courses.

In Advanced Mathematics Mr. Forsyth lectures on Thermodynamics, Mr. Glaisher on Theory of Errors, Mr. Webb on Dynamics of a System. The latter course will be continued during the Long Vacation, when also Prof. Darwin will lecture on the Theory of Attractions, Potential, and Figure of the Earth.

In Geology Prof. Hughes lectures on Stratigraphy and Cam-

bridge Geology, Mr. Marr on Advanced Palæontology, especially the Graptolites, Mr. Harker on Microscopic Petrology.

In Botany Dr. Vines is lecturing on the Cryptogams; Mr. F. Darwin on Physiology, and Mr. Potter on Advanced Systematic Botany.

In Zoology, Mr. Sedgwick continues the courses of Elementary Biology, and the Anatomy and Embryology of the Vertebrata; Mr. Gadow gives a summary Course on the Palæontology of the Vertebrata.

In Physiology, beside Prof. Foster's Elementary Course, we have advanced lectures by Dr. Gaskell, Dr. Hill, and Mr. Langley.

Prof. Macalister lectures on the Variations in the Skeletal, Muscular, and Nervous Systems of the Races of Mankind.

The Special Board for Physics and Chemistry report to the Vice-Chancellor on the new Mechanical Science Tripos:—

In consequence, the report states, of the Grace passed March 11, 1886, confirming their report, dated December 14, 1885, the Board have drawn up regulations for the New Tripos in Engineering, Physics, and Chemistry, for which they would propose the name "Mechanical Science Tripos." They do not think it desirable that the University should examine in subjects for which the University does not or may not easily provide adequate teaching, and have therefore made the examination in Engineering mainly an Examination in Mechanical Engineering. They have included, however, in it such elementary portions of Civil Engineering as can be taught in Cambridge and such as may often be advantageously studied by those who are intending to become Mechanical Engineers. With respect to the Engineering papers in Part II. of the Examination one paper would test the ability of the candidates to indicate how a given design should be carried into execution; another would include questions on steam and the steam-engine besides other prime movers, and also on boilers and furnaces; a third would include questions on bridges, roofs, arches, abutments, elementary hydraulics, strength of materials, and elementary building construction. In the Examination in Physics in Part II. the papers would contain questions on the application of dynamics to physical phenomena; gravitation; attractions; hydrostatics and hydrodynamics; properties of matter, including elasticity, capillarity, diffusion, and viscosity; heat; kinetic theory of gases; radiation; light, including the application of the undulatory theory to the problems of geometrical optics; mineralogical physics; acoustics; meteorology; cosmical physics; electricity and magnetism; reduction of observations. The Practical Examination would extend over two days, the Examination on the first day being of such a nature as would test the knowledge of the candidates in the general methods of laboratory work; on the second day a list of experiments would be given, one or more of which each candidate would be expected to complete.

SCIENTIFIC SERIALS

Bulletins de la Société d'Anthropologie de Paris, tome 8eme, 4me fascic., 1885.—On the facial and cranial muscles of a young gorilla, by M. Chudzinski. The subject of this post-mortem examination, a young male, was 98 centimetres in height. The muscles of the head and face were the same in number as in the human species, but in form and dimensions they exhibited certain differences, being combined into a single fleshy mass, which covered most of the face.—M. Pozzi laid before the Society various anatomical characteristics with reference to the comparative constitution of the muscles of the Negro and the white races.—M. Folley drew attention to the greater anastomosis of the subcutaneous abdominal veins of the Negro, and the importance of this peculiarity in giving to the organism a greater power of resisting the action of rapid variations of atmospheric or aqueous pressures.—On the common origin of Malays and Vedahs, by M. Beauregard.—On the universal language of F. Sudre, by M. Gajewski. The basis of the system proposed fifty years ago by M. Sudre is the musical nomenclature of the vocal notes, *do*, *re*, &c., and from these he elaborated a language which claims to be equally capable of expression by means of musical instruments and the voice. The defects and impracticabilities of Sudre's proposed musical language were considered at length by MM. Kerckhoffs, Dally, and Dehoux.—Suggestions for the modification of Broca's method of determining the direct absolute cranial capacity, by M. Topinard. The points chiefly insisted on are the different results yielded by fresh, and often-used, lead, the latter being valueless after 100 cubage determinations.—On the cause and nature of the vitrification observed in tumuli, and other ancient structures, by M. Manouvrier.—Report of the recent Anthropological Exposition at Buda-Pesth, by Dr. R. Blanchard.—On the dimensions and location of the dolmens of St. Nectaire, by Dr. Verrier.—History and anthropology, by Dr. Fauvelle. The writer draws attention to the tissue of errors which works intended for the instruction of the young continue to promulgate, as exemplified in the current historical explanations of the origin and usages of earlier races.—On the Gallic habitation of Mané Gobenne, Carnac, by M. Gaillard. The finds, which consisted principally of flints and pottery, included a string of twenty-three green serpentine beads cut into various forms.—On certain unique objects shaped like fishes, found in the Mammoth Cave in Varsovia, by M. Zawisza, and supposed to have been employed as fetishes by sorcerers.—On the significance of certain strongly marked impressions on the inner surface of a skull, by M. Manouvrier. Such impressions have been regarded as an evidence of imperfection in the cerebral convolutions, and of consequent mental deficiency.—On man of the age of Palæolithic pottery in the Lozère district, by MM. Martel and L. de Launay. The local finds attest the co-existence there of man and the cave-bear, and the fabrication of pottery at the time.—On the flint implements of Croix Fringant, near Cognac, by M. Germain.—On the calcareous islets of Taled Sah, in the inner sea of the Samsans, in the Malayan peninsula, and the natives who dwell in natural caverns and are engaged in collecting edible swallow-nests, by M. Macey.—On the displacement of the brain in accordance with the different attitudes assumed by the body, by M. Bonnard.—On the form of the hand and figure of Asiatics, by Dr. Mugnier.—Anthropometric and other observations of three Australians now being exhibited in Paris, by M. Topinard.—On the development of the cranium in the gorilla, by M. Deniker. It is found that, while the frontal region is developed, like other parts of the cranium, as rapidly in the gorilla as in man from the middle of fœtal life to the eruption of the milk molars, different relations supervene after the latter period, the cranial development of the gorilla becoming much more strongly marked in the posterior and inferior than in the anterior regions. At the same time the upper maxillary rapidly acquires its characteristic prognathic form. An almost equal degree of prognathism is observable in the adult Negro, or Australian, and in the infant gorilla, but with its growth the latter acquires a facial angle which is smaller than that of any human cranium.—Ethnographic observations on the cerebral function, by M. Fauvelle.—On a case of an hermaphrodite, by M. A. de Mortillet.—Notes on the post-mortem appearances of an imbecile, by MM. Doutrebente and Manouvrier.—Report, by M. Letourneau, on the Godard Prize Essay of M. de la Calle (1885) on the earliest attempt at speech in infants. M. de la Calle attempts to draw a parallel between the first enunciation of the vowel-sounds *a*, *e*, *o* by infants, and the monosyllabic character of certain languages belonging to various peoples of the far east of Asia, which have scarcely yet entered upon the more advanced stage of lingual agglutination.

SOCIETIES AND ACADEMIES

London

Royal Society, April 15.—"Dynamo-Electric Machines." By John Hopkinson, D.Sc., F.R.S., and Edward Hopkinson, D.Sc.

Omitting the inductive effects of the current in the armature itself, all the properties of a dynamo-machine are most conveniently deduced from a statement of the relation between the magnetic field and the magnetising force required to produce that field. This relation given, it is easy to deduce what the result will be in all employments of the machine, also the result of varying the winding of the machine in armature or magnets. The magnetic field may be expressed algebraically as a function of the magnetising force, or more conveniently by a curve (*Proceedings* of the Institution of Mechanical Engineers, April 1879, p. 246). Amongst the empirical formulæ which have been proposed to express the electromotive force of dynamo-machines in terms of the currents around the magnets, we may mention that known as Fröhlich's, where $E = \frac{ac}{1 + bc}$, E being the electromotive force of the machine at a given speed, c the exciting current, and a and b constants. For some machines this hyperbola is said to express observed results fairly accurately. In our

experience it does not sufficiently approximate to a straight line in the part of the curve near the origin, and gives too high results for large values of c.

One purpose of the present investigation is to give an approximately complete construction of the characteristic curve of a dynamo of given form from the ordinary laws of electromagnetism and the known properties of iron. Let n be the number of convolutions on the magnets, c the current round the magnets, l_1 the mean length of the lines of force in the iron of the armature, A_1 the area of section of iron in the armature, l_2 the distance from iron of armature to iron of pole pieces, A_2 the area of the magnetic field in which the wires move corrected for its extension round the edge of the pole pieces, l_3 the total length of the magnet cores, A_3 the area of the magnet cores, l_4 the mean length of lines of force in the yoke connecting the magnet limbs in machines of the type on which we have principally experimented, A_4 the area of section of the yoke, l_5 the mean length of the lines of force in each pole piece, A_5 the main area of section of pole piece, I the total induction through the armature when no current passes in the armature, and νI the total induction in the magnet cores; and, finally, let the relation between the magnetic force (α) and induction (a) (*vide* Thomson, "Electrostatics and Magnetism," p. 397, and Maxwell, "Treatise on Electricity and Magnetism," vol. ii. p. 24) be represented by the equation $\alpha = f(a)$, then the characteristic curve is—

$$4\pi nc = l_1 f\left(\frac{I}{A_1}\right) + 2l_2\frac{I}{A_2} + l_3 f\left(\frac{\nu I}{A_3}\right) + l_4 f\left(\frac{\nu I}{A_4}\right) + 2l_5 f\left(\frac{I_5}{A_5}\right).$$

If the relation between α and a be given in the form of a curve, this formula indicates at once a perfectly simple graphical construction for the characteristic. Taking the curve of magnetisation determined by one of us for wrought iron, and constructing a characteristic in this way, we have obtained a theoretical curve which agrees over a long range with the actual results of observation on a dynamo-machine more closely than any empirical formula with which we are acquainted.

To determine ν, a wire was taken once round the middle of one magnet and connected to a ballistic galvanometer, a known current was then either suddenly passed round the magnets or short-circuited, the elongation of the galvanometer being noted. A similar observation was made with the same current, the galvanometer being connected to a single convolution of the armature in the plane of commutation. The ratio of the two elongations is the value of ν.

The distribution of the waste field $(\nu - 1)$I was roughly ascertained in a similar manner.

The currents in the fixed coils round the magnets are not the only magnetising forces applied in a dynamo-machine. The currents in the moving coils of the armature have also their effect upon the resultant field. In well-constructed machines the effect of the latter is reduced to a minimum, but it can be by no means neglected. This introduces a second independent variable, viz. C, the current in the armature. The effect of the current in the armature depends upon the lead given to the brushes. Denote this by λ, which we may also regard as an independent variable, as it is subject to arbitrary adjustment.

If $I = F(4\pi nc)$ be the characteristic curve when no current passes through the armature, then

$$I + \frac{\nu - 1}{\nu} 4\lambda m C \frac{A_2}{l_2} = F\left(4\pi nc - \frac{4\lambda m C}{\nu}\right),$$

where m is the number of convolutions in the armature. Here we omit the comparatively unimportant portion of the magnetic force in the core of the armature and the pole pieces. From this formula it is not difficult to deduce a geometrical construction for the characteristic surface (*vide* "Practical Applications of Electricity," lectures delivered at the Institute of Civil Engineers, 1882–83, p. 98). The equation may be thus expressed in words, if λ be such that the coils at commutation embrace the whole or nearly the whole induction. The effect of the current in the armature upon the difference of potential between the brushes of any machine, is the same as that of an addition to the resistance of the armature proportional to the lead of the brushes, and to the ratio of the waste field to the total field, combined with that of taking the main current $\frac{m\lambda}{\nu\pi}$ times round the magnets in a direction opposite to the current c. Many consequences can be deduced, of which we may notice the following:—In a series-wound dynamo C is equal to c, and if c be increased beyond a certain point, I must attain a maximum and then diminish; this has been frequently observed. We now see that it depends upon the existence of a waste field. Secondly, let the coils of the magnets be entirely disconnected, and let λ be the negative; if the armature be short-circuited through a small resistance and be run at a sufficient speed, a large current may be produced in the armature. This latter deduction we have verified by direct experiment.

The efficiency of the type of dynamo-machine upon which the experiments before indicated have been made, has been accurately determined by the device of coupling two similar machines, both mechanically and electrically, so that one should act as a generator of electricity, driving the other electrically, whilst the latter acted as a motor driving the former mechanically; the loss of power required to keep the whole combination in movement being determined by direct dynamometric measurement, and the power passing electrically from the one machine to the other being measured by ordinary electrical appliances.

The whole of the experiments were carried out at the works of Messrs. Mather and Platt, to whom we are indebted for the exceptional opportunities we have enjoyed of putting theoretical conclusions to the test of experiment on an engineering scale.

Zoological Society, April 20.—Prof. W. H. Flower, F.R.S., President, in the chair.—Mr. O. Salvin, F.R.S., exhibited a living specimen of a foreign worm (*Bipalium kewense*), found in a garden in Sussex.—The Secretary read an extract from a letter addressed by Mr. R. A. Sterndale, F.Z.S., to Sir Victor Brooke, concerning a case of hybridism between *Ovis hodgsoni* and *O. vignei*.—Mr. J. Bland Sutton, F.Z.S., read a paper in which he gave an account of some of the investigations he had made during the past twelve months into the diseases affecting the mammals living in the Society's Collection.—A communication was read from Dr. O. Finsch, C.M.Z.S., describing a new species of wild pig from New Guinea, which he proposed to call *Sus niger*.—Mr. Smith Woodward read a paper on the relations of the mandibular and hyoid arches in a Cretaceous shark (*Hybodus dubrisiensis*, Mackie).—A communication was read from Prof. R. Collett, of Christiania, C.M.Z.S., containing an account of the hybrid between the willow-grouse (*Lagopus albus*) and the black grouse (*Tetrao tetrix*), which occurs occasionally in Norway, Sweden, and Northern Russia, and of which the author had examined altogether thirteen specimens, most of them of the male sex.—Mr. G. A. Boulenger, F.Z.S., gave the description of a new Iguanoid lizard living in the Society's Gardens, for which he proposed the name of *Ctenosaura erythromelas*. The exact locality was unknown.—A second paper by Mr. Boulenger contained remarks on specimens of a scarce European frog (*Rana arvalis*) exhibited in the Society's Menagerie.

Royal Meteorological Society, April 21.—Mr. W. Ellis, F.R.A.S., President, in the chair.—Mr. L. J. Petre and Mr. G. B. Wetherall were elected Fellows of the Society.—The following papers were read:—The climate of Killarney, by the Ven. Archdeacon Wynne, M.A., F.R.Met.Soc. The climate is determined partly by its geographical position, and it has the benefit of proximity to the south-west coast, with all the modifying influence of the Gulf Stream. The temperature, however, is locally modified, and a decided difference is found to exist between that of Valencia and of Killarney. The author shows that Killarney is colder than many other places in Ireland, and this he attributes to the fact that it is in a great irregular basin surrounded by mountain ranges for about a third, and by hilly ranges elevated some hundreds of feet above the lakes on most of the remaining two-thirds of the circle.—Note on the probability of weather sequence, by Lieut.-Col. C. K. Brooke, F.R.Met.Soc.—Account of the cyclone of June 3, 1885, in the Arabian Sea, by Capt. M. T. Moss. The author, who was in command of the s.s. *Inchulva*, while on a passage to Bombay had, when near Aden, the misfortune to encounter a most furious storm on the above date. This storm, which was apparently not of very large dimensions, was exceedingly severe, and was accompanied by an immense wave which caused several fine steamers to founder.—Results of solar radiation observations in the neighbourhood of Birmingham, 1874–84, by Rupert T. Smith, F.R.Met.Soc.—Results of meteorological observations made in the Malay Native State of Selangor during 1884, by A. W. Sinclair, L.R.C.P. These observations were taken at four stations, viz. Kwala Lumpor, Klang, Kajang, and Kwala Langat. The mean temperature of the district is about 80°, and the rainfall about 90 inches.

DUBLIN

University Experimental Science Association, March 16.—The following communications were made:—Prof. J. E. Reynolds, on action of silicon tetrabromide on thiocarbamide.—Mr. H. L. Crosthwait, the Forth Bridge.—On the melting-points of minerals, by J. Joly, B.E. An account of experiments with the meldometer, in which the temperature of the platinum strip, acting as the stage of a microscope, was determined in terms of its resistance according to Siemens's formula. It was mentioned that the order of fusibility assumed in Van Kobel's scale is erroneous. The true order seems to be: (1) stibnite; (2) natrolite; (3) adularia; (4) actinolite; (5) bronzite; (6) almandine. The blowpipe being a powerful chemical agent, may evidently mask the phenomena of fusion with secondary effects. Fair comparison is impossible with it, the shape and conductivity of the specimen used affecting the result. Comparison on the meldometer is not open to these objections. It is very advisable that a scientific scale of fusibility should be adopted for the use of mineralogists. If this scale rested on the melting points of easily-prepared salts, it would then always be easy to determine by comparison the melting-point of a mineral. Approximate determinations could thus be readily effected on very minute quantities of matter. In the author's experiments the substances are reduced to a fine powder, the phenomena attending fusion being observed with a 1″ object-glass. These phenomena are often very characteristic and beautiful.

PARIS

Academy of Sciences, April 27.—M. E. Blanchard in the chair.—On the quantitative analysis of the organic carbon contained in soils which absorb free nitrogen, by M. Berthelot. The author's researches on the direct absorption of free nitrogen by various argillaceous soils through certain minute organisms have led him to seek some other measure capable of indicating the proportion of these organisms in the ground. It being apparently impossible to isolate them, some idea of their abundance may still be formed by a quantitative analysis of the carbon entering into the constitution of their tissues. Hence the present inquiry, which promises to raise some new and extremely delicate problems.—Observations relative to the proportion and quantitative analysis of the ammonia present in the ground, by MM. Berthelot and André. The experiments conducted during the last four years by the authors at Meudon on the general growth of vegetation and on the formation of nitric compounds, both in plants and in the soil, have led to certain observations here communicated on the processes employed in the quantitative analysis of the ammonia and the starchy compounds. It is inferred generally that the analysis of the ammonia present in the soil should be made without any desiccation, and that arable ground, when watered, tends continually to liberate the ammonia of the ammoniacal salts contained in it.—On the nitric substances contained in rain-water, by MM. Berthelot and André. A process is explained for determining by analysis the exact quantity of nitric substances conveyed to the earth by meteoric waters.—On the movements of meteorites in the atmosphere, by M. Faye. These remarks are made in connection with M. Daubrée's essay on "Meteorites and the Constitution of the Terrestrial Globe," recently presented to the Academy by the author.—Discourse pronounced at Montdidier on the occasion of the celebration of the Parmentier centenary, by M. Chatin.—Note on the meteorological observations made at the Montpellier School of Agriculture since last summer with the registering actinometer, by M. A. Crova. The results already obtained for the variations of solar radiation in summer require to be modified for the autumn and winter seasons. In autumn the oscillations diminish in amplitude, the two maxima of heat intensity tending continually to approach each other and gradually merge together about noon in winter.—Note on M. Lœwy's formulas for the reduction of the circumpolar stars, by M. Gruey. A process, at once simple and easily remembered, is given for establishing all M. Lœwy's formulas without any sacrifice of accuracy.—Remarks on the appearance of Fabry's comet in April 1886, by M. G. Rayet. The comet, observed at Bordeaux on April 7, 13, and 21, exhibited a very long continuous spectrum from the extreme red to the violet, corresponding with the light of the nucleus and of the three ordinary bands of cometary spectra.—Note on the equilibrium of a fluid mass in rotation, by M. H. Poincaré. Some explanations are offered in connection with M. Matthiessen's note inserted in the *Comptes rendus* for April 12.—On the magnetic rotatory power of the crystalline bodies, by M. Chauvin. Iceland spar and some other birefractive crystals, supposed by Faraday and others to be inactive, are shown to possess the property of magnetic rotation.—Action of alcoholic potassa on urea, sulpho-urea, and some substituted ureas; inverse reaction of the artificial urea prepared by Wöhler's process, by M. Alb. Haller.—Note on two properties of the urethanes of the fatty series, by M. G. Arth.—On the abnormal secretion of nitric substances in yeast and mould, by MM. U. Gayon and E. Dubourg.—Remarks on *Polystigma fulvum*, Tulasne, a new disease of the almond-tree, by M. Maxime Cornu.—Propagation of the luminous sensation to the non-excited zones of the retina, by M. Aug. Charpentier. From his optical experiments the author concludes that, in the phenomenon of successive luminous induction, the nervous action which gives rise to the sensation is really transmitted to the parts of the percipient medium lying near the excited part.—An attempt at a physiological explanation of the phenomenon of complementary colours, by the late M. Trève.—Heliophotography and the magnetic perturbation of March 30, 1886, by M. Ch. V. Zenger.—Observation of an aurora borealis at Rolleville, Seine Inférieure, coincident with the magnetic perturbation of March 30, by the Abbé Maze.

BERLIN

Physical Society, February 19.—Dr. Pernet reported on the part he had taken in the labours of the International Commission which had for their object the comparative determination of the normal metre. After recounting in a brief historical survey the undertakings carried out in Paris at the end of last century by an International Congress, which, after theoretically determining on the kilogramme and the metre as normal units, produced a normal metre and normal kilogramme of platinum, the speaker discussed the events which in 1878 led to a new international agreement, in consequence of which a new normal metre of platinum-iridium of X-form was prepared and compared with the metre of the Archives. A series of national standards was also compared with the normal metre. The speaker described in a searching manner the arrangements of the Bureau in which the comparisons were undertaken, the contrivances for securing the several comparing rooms against outward disturbances, the means adopted for insuring constant temperatures, and the methods employed in the comparisons, as also in the determination of the expansion coefficients of the rods used. Finally he gave a sketch of his own labours, which had for their object the comparison of a series of normal metre rods of different metals with the metre of the Archives, and the determination whether repeated heatings and coolings between 50° and 0° C., whether concussions, and whether time caused any perceptible changes in the lengths of the rods. As the result of these investigations it was found that the compared national standards, together with their divisions, were exact up to one-thousandth of a millimetre; that, with the exception of steel, which, on account of its changes in hardness, readily yielded modifications of volume and length in the rods made of this material, all the metals out of which the standards were made—namely, platinum-iridium, platinum, and brass—furnished material suitable for normal metre rods; and that repeated heatings and concussions induced no changes passing beyond the limits within which observation fails.—Herr C. Baur described experiments he had made with water-jets, which, issuing from a conically-pointed tube in parabolic curves, were acted upon by certain musical tones so that at some distance from the mouth of the tube they showed a rotation, and that the jet, though broken up into drops behind the apex of the parabola, contracted into a continuous jet. The thinner was the jet the higher must be the tone towards which it was sensitive; the thicker the jet the deeper the tone. Herr Baur had instituted further experiments with water-jets, which he caused to fall on plates. Under certain circumstances there thus arose quite pure tones, which continued as long as the jet hit on the plate. The experiments succeeded best with a Weissmann apparatus, when the jet issued under a pressure of 10 cm. water from a lateral opening of 4 mm. in diameter without tube. Thin window-glass plates and metal plates, which, resting on pedestals, had free movement of vibration, were best suited as receiving-plates. The tone was most certain of occurrence when the node lines of the plates were supported. In the jet itself appeared nodes and ventral segments at some distance from the opening; they were most distinct and regular at its middle; away in the direction of the plates they again became indistinct. If the metal plate

and the water acidified beforehand were connected with a galvanic cell and a telephone, then no interruptions of the current could be recognised during the time of the sounding. The contact of the water-jet with the plate must necessarily therefore be continuous. Herr Baur deemed this mode of excitation very well adapted to the purpose of studying the vibrations of plates. In the discussion following this address it was pointed out from various sides that more than twenty years ago Prof. Tyndall and after him Magnus had instituted experiments respecting the action of tones on water-jets, and that Prof. Tyndall had at the time shown his experiments to the Physical Society in Berlin.

Physiological Society, March 12.—Dr. Gad reported on the experiments he had made on the subject of hæmorrhagic dyspnœa which he had referred to in his last address. If by opening a cannula inserted into the aorta a large supply of blood were taken from an animal, dog or rabbit, then dyspnœa at once ensued, and that in the form of increased inspirations, such as showed themselves in all cases of dyspnœa induced by insufficient conduction of oxygen to the respiratory centre. These heightened inspirations proceeded side by side with a conspicuous sinking of the blood-pressure, and were denominated by the speaker "pneumatorectic" respirations. This respiration was distinguished from normal respiration by regular deep inspirations of unchanged frequency, inspirations in which the middle attitude of the thorax removed farther from the expiratory than was the case in normal respiration. The curve of respiration either then passed over into the normal, or convulsions set in, in which case the blood-pressure rose and the respiratory curve grew altogether irregular. After repeated heavy discharges of blood, the pneumatorectic passed into the "syncoptic" respiration, which was characterised by deep inspirations of very infrequent occurrence, during which the attitude of the thorax after expiration approximated ever nearer to that which it held in a dead body, till the last breath, and so the death of the animal, occurred. These two kinds of respiration, the pneumatorectic and the syncoptic, were perfectly regular and typical; the former showed itself immediately after a heavy discharge of blood, the latter before death. Between these two extreme forms there passed a series of others in an inter-current manner. Of these there was first to be mentioned a very frequent superficial respiration, which was inadequate to the necessities of the organism, and had the name "hypokinetic" applied to it. If the animal recovered out of this stage, the hypokinetic passed into the pneumatorectic and the normal respiration, otherwise it was followed by the syncoptic respiration and death. The transitional process from the hypokinetic into the pneumatorectic respiration might be experimentally brought about in a perfectly regular manner by the injection into the venous system of warm physiological solution of common salts. With the increase of the blood-pressure the alteration in the form of respiration at once asserted itself, the respiration becoming sufficient. Even at the stage of syncoptic respiration a transition into the pneumatorectic respiration might occasionally, though not always, be induced by injection of solution of common salt, and in that way the life of the animal be rescued. Another form of respiration following heavy bleeding was that which showed itself in periodical increasings of the amplitudes in respiratory movements. These and diminishings of amplitudes ran parallel to the Traube-Hering periodical oscillations of the curves of blood-pressure, though with displacement of the phases. The periodical oscillations in the amplitude of respiration referred to formed a transition to the Cheyne-Stokes phenomenon. The speaker recounted the explanations of the Cheyne-Stokes respiration, and took sides with the older theory, according to which it was to be conceived as a rhythmus of activity on the part of the central organs having periods of a higher order than had the simple rhythmus of respiration. In conclusion Dr. Gad drew from his physiological experiences a series of practical consequences having respect especially to the suitability of transfusions of common salt after heavy bleedings, particularly at the stage of hypokinetic respiration.—Prof. Zuntz spoke of the nature of the stimulations regulating the normal respiratory movements. The every-day experience that increased muscular activity produced an increased respiratory activity, dyspnœa, had suggested simultaneously to the speaker and to Dr. Geppert the idea of investigating whether the gases of the blood, which were universally assumed to be the sole stimulations of respiration, were adequate to the explanation of this dyspnœa. The experiments respecting which the speaker delivered a report were instituted in common. From the carotid artery of an animal habituated to regular work—a draught dog—were taken quantities of blood which sufficed for the purpose of analysing the gases of the blood. The quantities of blood referred to were taken on one occasion while the dog was in a state of rest, lying comfortably at his ease in his cage; or on another occasion while the dog was at work pulling a loaded car in his usual manner. By an ingenious contrivance, which the speaker described, the discharge of blood was rendered possible without the dog noticing anything of the matter. In a similar manner, by special apparatus, without molesting the dog in any way, they were enabled to measure the quantity of the air breathed in a given time, and to take away small quantities of the exhaled air to be subjected to analysis. The examination of the blood-gases showed that the arterial blood during work contained less carbonic acid and more oxygen than it did during a state of rest. During work the blood contained about 39 per cent. CO_2, and in a state of rest about 40 per cent.; the amount of oxygen, on the other hand, was about 18 per cent. during work, and about 12 per cent. in time of rest. The respiratory activity was, however, during work considerably increased. The quantity of exhaled air during work increased to threefold that exhaled in time of rest, and, corresponding with the increased respiratory activity, the air exhaled during work showed a less increase of CO_2 and a smaller loss of oxygen than in time of rest. The increased respiration during work could not now be caused by the blood-gases, seeing that the contents of the arterial blood in CO_2 were less, and in oxygen considerably more, than during a state of rest. Another stimulus must accordingly act on the central organs of respiration during work. It was possible to imagine that, along with the voluntary excitation of the muscles of the body during work, the respiratory muscles might likewise be stimulated, or that from the corporeal muscles contracting themselves during work a stimulus proceeded reflexively exciting the respiratory centres. The following experiment, however, was against both of these possible assumptions. The spinal marrow of an animal was intersected at the top of the thoracic vertebra, and the paralysed lower extremities tetanised while the anterior part of the body remained at rest. Notwithstanding, however, that all nervous connection between the working muscles and the respiratory centre was cut off, the dyspnœa of work still ensued, and disappeared when the tetanus ceased. From this fact the speaker drew the inference that in the active muscle some product or other was generated which arrived with the blood at the respiratory centre and excited it. The accuracy of this conclusion was further confirmed by the following experiment. The abdominal aorta of the animal with intersected spinal marrow was, during the tetanus of the posterior extremities, strongly compressed through the abdominal integuments. The respiration now continued unchangedly normal, nor did any dyspnœa ensue so long as the compression lasted. Dyspnœa showed itself, however, the moment the compression was removed. Even when the aorta was left free after the tetanus was ended, increased respiration still occurred. The speaker conceived therefore he had conclusively established that a substance, still unknown, forming itself during the muscular activity, proceeded with the blood to the respiratory centre and excited it. He conjectured that, in other active organs as well, such an efficient substance developed itself as respiratory stimulus, a substance which operated along with the gases of the blood even in the normal respiration. In the discussion following this address, Prof. Zuntz mentioned that Dr. Lehmann had made some experiments respecting the effect of acids on the respiratory centre, and had found that the acids excited this centre. This excitation was of course not powerful enough to justify the conclusion that the acid produced during the muscular contraction was the respiratory stimulus in the dyspnœa of work.

Meteorological Society, April 6.—Prof. von Bezold, the newly appointed Director of the Meteorological Institute in Prussia, which is to be reorganised, explained the principles in accordance with which the reorganisation in question would be undertaken. He first gave a short survey of the history of meteorological observations, setting forth how, first, the disciples of Galileo in the Academia del Cimento made use of the newly invented instruments for the observation of temperatures and atmospheric pressure; how, next, as early as the beginning of the eighteenth century, several investigators of nature had arrived at the knowledge that meteorological observations of any

comprehensiveness could be successfully instituted only through the association of a considerable number of observers; and how, more than a hundred years ago, the Societas Palatina in Mannheim had organised an extended network of stations of observation, at which observations were instituted with instruments of the same construction, according to the same plan, and at the same times, and were collected at the central office, and published in a manner which would be deemed exemplary even if issued at the present time. This work was prosecuted till the French Revolution put a termination to it. In Prussia the suggestion of a meteorological institute was made by Alexander von Humboldt, and was crowned with success only in 1847, when, on Humboldt's proposal, Mahlmann was made the first Director of the Meteorological Institute, which was connected with the Statistical Bureau. In 1849 Dove succeeded Mahlmann as Director of the Institute, and held the post till his death in 1879. Meanwhile, however, the necessity of a complete transformation of the Meteorological Institute came to be recognised. Formerly, simple average values for the different stations were calculated, and for these no special stress was laid on the single observation, in consideration that mistakes balanced one another. Now, however, when it was a question of preparing synoptic maps and of obtaining exact maps of the meteorological conditions prevailing at a determinate time over a large area, the value attached to the single observation was a much higher one, and it was of the greatest importance that all the data should be as free from error as possible. It would accordingly be the first task of the Institute to provide all stations of the second and third order with good instruments, carefully to see they are maintained in good order, and to collect the materials of observation. The network of stations of observation would have to be completed and equally distributed, and there were about 200 stations of the second and third order, besides some thousands of subordinate stations, in contemplation. The subordinate stations should be equipped with rain-gauges, and make observations on precipitation, thunderstorms, and such like. A second problem of the Institute was the exact determination of the course of the meteorological elements for the day, the month, and the year, by uninterruptedly continuous observations not only of the climatic factors—temperature, atmospheric pressure, moisture, &c.—but also of the phenomena of the earth's magnetism and electricity. This work would be done by the Observatory, which was completely separated from the Meteorological Institute. The Observatory, under a special direction, was transferred to Potsdam to the Astro-physical Observatory. Two similar Observatories of the first rank, one in Breslau, perhaps, and one in Bonn—at all events, in University towns wide apart from each other—were in contemplation. While the Observatory prosecuted its observations in the quiet of Potsdam, the Meteorological Institute should have its seat in the midst of Berlin, in the edifice of what was formerly the Building Academy, and continue in connection with the lively intercourse of the capital. Irrespective of the service for weather warnings to be introduced perhaps at a later date, which would require to be in proximity to the head telegraph office, the central position should be readily accessible to the different observers who came from the provinces to the capital. The Institute, moreover, should be easily available for all students of science and experts who were in need of meteorological data: such, for example, as agriculturists, physicians, persons engaged in hydraulic labours, &c. The Meteorological Institute should, finally, have as its main function that of being a teaching institute for the scientific training of meteorologists. Its function in this respect should not be merely confined to lectures at the University, but should especially consist of practical work done, under the guidance of assistants, by students and young observers in the Meteorological Institute, similar to what is carried on in chemical, physical, and other laboratories. With this programme in hand, the new Director hoped very soon to bring the Meteorological Institute to the degree of efficiency attained by similar institutes in neighbouring countries, and particularly by the teaching thus imparted to cultivate a new field fruitful of good results for science.—Dr. Weinstein, with reference to his paper recently read to the Society, made some further communications respecting disturbances of the earth's currents which had occurred on January 9 and March 30. On March 30 the disturbances were so great that in the course of the forenoon telegraphic communication in Germany was stopped. Even with currents of 60 Daniells no signs could be forwarded by the telegraph wires. The magnetic elements in Wilhelmshaven showed great simultaneous disturbances, and from the direction of these magnetic disturbances it was inferred that the disturbances of the earth's electricity were the primary, the oscillations of the earth's magnetism the secondary.—In connection with these observations of Dr. Weinstein, Prof. Spörer stated that from March 26 to April 4 a very remarkable and numerous group of spots had been observed on the sun. On March 30 Dr. Less had observed squalls, accompanied with remarkable oscillations of temperature and of atmospheric pressure, and Dr. Assmann read several reports on North Light phenomena which had been perceived on March 30 in Eldena, Greiffenhagen, Magdeburg, and Nordhausen.—Dr. Weinstein further communicated that Prof. Förster had entered into an arrangement for having reports of disturbances observed in the earth's current at once forwarded to the Astronomical Observatory that the state of the sun might be simultaneously examined.

THE CHEMISTRY OF THE COAL-TAR COLOURS

The Chemistry of the Coal-Tar Colours. Translated from the German of Dr. R. Benedikt, and Edited, with Additions, by E. Knecht, Ph.D. (London: George Bell and Sons, 1886.)

THIS is an excellent little practical manual dealing with a subject of great scientific and industrial importance—a subject the scientific side of which has been somewhat neglected in this country, to the inevitable detriment of the industrial side. The decline of this industry in England is a tempting subject to expatiate on; but the moral has of late been pointed with such laudable iteration that we refrain from pointing it afresh. The state of affairs which prevails with regard to the literature of the subject is expressed in the opening words of the editor's preface:—

"Although England may be called the birthplace of the coal-tar-colour industry, it is a remarkable fact that the English literature on the subject is very scanty, and that which does exist is now almost obsolete owing to the rapid strides which have been made during the last ten years in the manufacture of the coal-tar colours."

There is no doubt about the want, and we think that this little work supplies it to the extent aimed at. Both author and editor are specially qualified for their task by experience in teaching the technology of the subject.

The work contains excellent introductory chapters on the optical properties of colouring matters, the methods of testing colouring matters—both spectroscopically and with regard to their tinctorial power—on the relation of the various fibres to the colouring matters, and kindred general questions, of importance both to the colour chemist and to the dyer. "Rule-of-thumb" is everywhere excluded; reasons are fully and clearly given.

The greater part of the work is necessarily devoted to the chemistry proper of the coal-tar colours—the chemical processes by which the various colouring matters are obtained and the reactions by means of which a knowledge of their chemical constitution is arrived at. Constitutional formulæ naturally play a very important part.

Our modern dynamical chemists—some of whom, by the way, appear to be censors first and investigators afterwards—are never tired of crying out for the abandonment of these constitutional formulæ on the ground that they afford only statical, not dynamical, representations of chemical phenomena. Happily, those who have built up the German coal-tar-colour industry of the last fifteen years on the basis of the benzene theory have never shared this opinion; nor is it shared by our authors, who in their little treatise faithfully reflect the methods and results of this great scientific and industrial development. Doubtless, colour chemists would prefer a dynamical formula—one which should indicate, for example, the most suitable temperature at which to perform a potash fusion, or a nitration, with a few hints thrown in as to time of heating, concentration, and so forth—and doubtless the dynamical chemists will in time supply this want; but meanwhile the colour chemist feels, taught by experience, that his humble and inexact calculus of chemical operations, the constitutional formula, is vastly better than anything that has been offered in its stead. But as yet the dynamical critic does not appear to have anything to offer in its stead: like certain *dynamitical* critics he is satisfied with destruction, and his attitude towards constitutional formulæ is not unlike that of the dynamitical critic towards Constitutions—British and other.

There is little which calls for criticism in the chemical portion of the work: the classification is good, and the results of the elaborate investigations of which almost every colouring matter of any importance has of late years been made the subject are given briefly but in a way calculated to make clear to the beginner the significance of such work. We could have wished, however, that Dr. Knecht in his editorial capacity had thought good to give some account of the researches of O. Fischer on flavaniline and chrysaniline, and of Bernthsen on methylene-blue. The problem of the constitution of these compounds has been solved in a very instructive and conclusive fashion—much more conclusively than in the case of some of the colouring matters of which the constitution is discussed in the present work.

In the introduction reference is made to the popular prejudice which exists against the so-called "aniline dyes"—the collective name by which coal-tar colours are known among non-chemists. There is an impression that the tints are crude and glaring, and that the colours lack fastness. Certainly there are coal-tar colours which sin in all these respects. But there is a survival of the fittest here as elsewhere: the vulgar shades and fugitive colours are being weeded out and replaced by better. The accusations come most frequently from persons of an æsthetic turn, and it is perhaps too much to expect that the strenuous æsthete, living laborious days in the endeavour to improve his own taste and that of his neighbours, should be aware that the beautiful and permanent Turkey-red, which he so justly admires, is now a coal-tar colour, and that even indigo may be made from coal-tar. As regards "fastness" of colours, the ideas of the general public on the subject may perhaps be gauged by a speech which we remember reading, made some years ago by a Member of Parliament in distributing the prizes at a technical school. Seeking to inculcate the duty of thoroughness in work, and desirous at the same time to employ only such illustrations as would at once come home to every technologist, he said:—"But it would not be thorough work, for example, to daub a wall with untempered mortar, or *to dye with fast colours*." Probably a life divided between politics and sport had not permitted him to realise that the fastness of colours is distinct from that of race-horses—or of youth!

Where there is so much to praise we regret to have to record a defect, but we think that hardly adequate care has been bestowed upon the proof-reading. The misprints are unnecessarily numerous, and must sometimes be very puzzling to a beginner, especially where, as is occasionally the case, they affect complicated formulæ. A list of errata is given, which, however, needs extension. Whether, for example, the chemistry of the average student of technology will be equal to the task of informing him that not sodium bisulph*ate*

but sodium bisulph*ite* is employed in the preparation of soluble alizarin-blue, or that the three formulæ given on p. 70 in a preliminary account of the products from tar, and described as those of "the three isomeric dinitrobenzenes," are in reality those of the three mononitrotoluenes—errata not corrected in the list—is open to doubt.

In conclusion, we cordially recommend the book. We trust that it will not only be made use of by students of technology as a useful introduction to the larger treatises in French and German, but that the ordinary student of organic chemistry will take the opportunity of making a closer acquaintance with a special branch of his subject, as fascinating from a scientific point of view as it is fertile in practical results. F. R. JAPP

JAPANESE HOMES

Japanese Homes and their Surroundings. By Edward S. Morse, Director of the Peabody Academy of Science. (London: Sampson Low, 1886).

ALTHOUGH Prof. Morse's connection with Japan has been comparatively short and interrupted, few men have done so much for scientific progress in that country. About ten years ago he first visited Japan in order to study certain forms of ocean life on its coasts, and, fortunately, was induced to accept the Chair of Zoology in the University of Tokio. While holding this office he did much to arouse an interest in the minds of his students for biological research, and he established a Biological Society, which is, we believe, still at work. By his discovery and thorough investigation of the shell-mounds at Omori, near Tokio, he stimulated prehistoric studies. His monograph on these mounds—although perhaps his theory as to the builders may not, on more extended examination, have proved tenable—was followed by a number of publications on the Japanese Stone Age, cave-dwellers, and the like; and in many less generally known directions his influence on the advance of science in Japan has been a beneficial and stimulating one. His first visit to Japan has been followed by two others, during which he visited all parts of the country, as well as other regions of Eastern Asia, and has collected material on a variety of matters. The present volume is a monograph on the house in Japan;—the different types of houses, their mode of construction, the uses of each part, the varieties in each from the roof to the foundation, the types and uses of household utensils, &c. The illustrations, which are beautiful, are also very numerous, being, on the average, about one to a page. Without them it would, indeed, be difficult for readers who are not well acquainted with Japanese houses to follow the descriptions. Many of these details Prof. Morse thinks it may soon be difficult, if not impossible, to obtain, and therefore like an old Japanese to whom he refers, and who "held it a solemn duty to learn any art or accomplishment that might be going out of the world, and then to describe it so fully that it might be preserved to posterity," he now describes and copies them for the benefit of future generations who may not have the opportunity of seeing these evidences of Japanese skill and sense of beauty. We do not apprehend that the Japanese will ever change so far as to substitute the jerry-builder for their own carpenters, and we do not think that their style of architecture will ever greatly alter, for the simple reason that they have now what, on the whole, is the fittest. Nevertheless we cannot but be grateful to Prof. Morse for making the Japanese house, inside and out, so familiar to English readers. His work is so clear and detailed that we see no reason why any one who feels so disposed should not be able to erect for himself a home in the Japanese style in England.

In the eighth chapter indications from the most ancient works in Japanese literature are collected together in order to catch a glimpse of what the Japanese house of a thousand years ago was like. It would be useless without a plan of the modern house before us, to refer to these beyond quoting Prof. Morse's conclusion that they are significant indications of the marked southern affinities of the Japanese, and he thinks that, from all we can gather relating to the ancient house of the Japanese, it would seem that certain important resemblances must be sought for in Annam, Cochin China, and particularly in the Malay peninsula—but not amongst the Ainos. This is another nail in the coffin of the theory of an ethnic relationship of the latter with the Japanese. On the whole, Prof. Morse's theory of the history of house development in Japan is a slow but steady progress from the rude hut of the past to the curious and artistic house of to-day—a house as thoroughly a product of Japan as is that of the Chinese, Corean, or Malay a product of these peoples, and differing from all quite as much as they differ from one another. It has just those features incorporated into it that might be expected from its physical proximity to, and historical relations with, China and Corea. The last chapter deals with the "neighbouring house"—that is, Corean, Chinese, Aino, and Loochooan houses. In this chapter the writer has fallen into a curious error in describing Hachijô Island as one of the Bonins. There is no more connection between the two than there is between Iceland and the Isle of Wight. Hachijô has from the earliest times been Japanese; it was at one time a place of exile for political offenders. The Bonins never belonged to Japan until within the last few years; as the name (*Bu* or *Mu Nin*, without people) implied, they were uninhabited, except by a few waifs and strays thrown up by the sea—Caroline Islanders, deserters from whalers and ships of war. The account of the visit to Hachijô, from which Prof. Morse quotes, was published some years ago in the *Transactions* of the Asiatic Society of Japan, and is of exceptional interest, for in this island may still be observed ancient Japanese customs which have long fallen into desuetude on the mainland. Thus the peculiar lustration ceremonies, the special parturition houses, &c., now found in Hachijô, are mentioned in ancient Japanese works as common to all Japanese. The difficulty of access to the island from the adjacent mainland on account of dangerous currents would explain the presence of this little oasis of antiquity. There is this excuse, however, for Prof. Morse's confusion of the Bonin Islands with Hachijô, that the expedition set out for the Bonins, but the writers about Hachijô went no farther than that island, and there, while awaiting the return of the steamer, collected the material for the paper in question.

ACOUSTICS, LIGHT, AND HEAT

Acoustics, Light, and Heat. By William Lees, M.A., Lecturer on Natural Philosophy, the Heriot Watt College, and Lecturer on Mathematics and Experimental Physics, Free Church Training College, Edinburgh. New and Enlarged Edition. (London and Glasgow: Wm. Collins, Sons, and Co.)

THIS is one out of many of the text-books which have been called into existence by the "May" Examinations of the Science and Art Department. Being written especially to meet the requirements of the student who wishes to pass these examinations, it is only brought up to the standard given in the directory of the Department, and may therefore for this purpose be useful. The fact that a new and enlarged edition is now appearing is certainly evidence that this is the case. To make it more serviceable, the questions of all the May Examinations in Subject VIII. from 1872 to 1885 are given.

Though the simple and numerous diagrams and the generally clear nature of the text give it a certain value as a text-book, it is by no means so free from faults and ambiguities as might be expected in a new edition.

It may be well to refer especially to a few places where alterations suggest themselves.

Figs. 19 and 20 show the contrast between a musical sound and a noise. Though it is explained that "noises are due to irregular vibration or a confused mixture of musical sounds which produce aërial waves of great complexity and wanting in periodicity," no explanation is offered of a peculiarity in the "curve of a noise" (Fig. 20), which in three places is actually made to slope backwards.

Some of the figures in optics are rather wanting in precision. Thus in Fig. 73, which shows a real image formed by a concave mirror, a pair of slightly diverging rays are made to cross between the mirror and the principal focus. Again, Fig. 77 shows a caustic on the surface of milk in a glass with its cusp reaching close to the centre. Fig. 103 shows the action of a refracting plate on a beam of light by the turning and approximation of successive wave-fronts. Those two wave-fronts which obliquely cut the surface are shown straight and partly swung round, as if they were rigid lines meeting with resistance at one end. It would surely have been better to have bent the line at the point of intersection, leaving all the wave-fronts and parts of a front outside the medium parallel to one another, and also all inside parallel to one another, but it is possible that wave-fronts, strictly speaking, are not intended.

The explanation of so important a thing as the achromatic lens can hardly be considered satisfactory. Owing to its brevity it is possible to give this in full. "This defect in a lens [the defect of chromatic aberration] is obviated by the combination of a double convex lens of *crown* glass, with a convexo-concave of *flint* glass (Fig. 122). The effect of the second lens is to re-blend the coloured rays which the first has produced, and at the same time such an amount of refraction is preserved as to bring the light to a focus." As nowhere is it directly pointed out that for the same degree of refraction flint glass produces more dispersion than crown, it is not difficult to imagine that a student might fail to form any very clear idea of the principle of the achromatic lens, nor is he likely to be materially helped by the figure (122), which certainly does not represent either the section or any other view of any achromatic lens that was ever made. If it were not for the section lines it would be a good perspective drawing of a short cylinder; the ellipse which appears to be the end of such a cylinder is really meant to show the crown lens in section, and the figure of uniform thickness by its side, as thick everywhere as the ellipse is in the middle, which seems to be the side of the cylinder, is meant for the section of the flint lens. Simplicity in a diagram is a thing to be desired, but there is more than simplicity here.

Very little is said about spectrum analysis; and its application to the measurement of the motion of the heavenly bodies in the line of sight is not even mentioned.

The general weakness of the optical part is to a certain extent compensated for by the chapters on polarisation, which have much to recommend them. There is here, however, a paragraph which requires explanation. "Now it is found that whatever quantity of polarised light there is for any incidence *other than the polarising angle* in the reflected beam, there is always the *same* quantity in the refracted beam. At the polarising angle, however, the refracted beam exhibits traces of polarisation." What is meant by this distinction is by no means clear.

Heat is more precisely and clearly treated than light, but here the general excellence is marred by an example to illustrate expansion in which the working out of the result shows that the obvious meaning of the question is not intended. What any one would understand by the words, "Find the length of a rod of brass which would expand equally with a rod of steel 3 feet long under a change of temperature of 10° C.," is evidently —Find what length of brass will increase in length by the same amount that a 3-foot rod of steel does for a change of 10° C. But what is found in the working of the answer is the length of a piece of brass which will expand so as to be *as long as* a piece of steel 3 feet long when each is *raised* 10° C.

Sufficient has been said to show that this book is not as clear and accurate in either the text or the figures as might be expected in a new edition.

OUR BOOK SHELF

Cholera Curable. By John Chapman, M.D. (London: Churchill, 1885.)

DR. CHAPMAN has had the opportunity of testing, in the Hôpital de la Charité in Paris, his method of the so-called neuro-dynamic treatment in Asiatic cholera, and his demonstration of the success of this treatment constitutes, we take it, the cardinal motive for the production of this book, although a good many other, mostly theoretical, considerations are brought into the discussion.

The symptoms of Asiatic cholera are explained by a number of assumptions on the action of the spinal cord and the sympathetic nervous system, but as to which we look in vain for experimental proof. The theories concerning the etiology and causation of cholera are fully treated, and then Dr. Chapman promises to furnish us with a complete solution of these problems in a discovery made by him as to the cause of cholera. When, however, we come to analyse what he really has discovered,

it turns out that he himself is moving in a circle of fallacies. While denying the specific nature of the cholera virus, he explains this latter by the symptoms of the disease. Assuming, for the sake of argument, with Dr. Chapman, the particular disturbances of function in the cord and the sympathetic nerves to which the symptoms of cholera are due, how does this bring us nearer to the knowledge of what causes these particular disturbances? By saying, or even by showing, that such and such a disturbance in the function of the cord and sympathetic causes such and such a symptom of disease, we are not one iota nearer the answer to the question, Why did such and such a disturbance take place? what has caused it? The answer to this one wants to know, but this is not supplied by Dr. Chapman. It is quite true that a great many conditions are required to favour the outbreak and spread of cholera, *e.g.* conditions of temperature, water, atmospheric disturbances, soil, &c., &c., but all these conditions may be present without producing cholera, or typhoid fever, or any other similar disease. Why? Because *the actual cause* of the disease is absent. These two things, viz. secondary conditions favouring the outbreak and spread, and *the actual cause*, must be kept separate; but evidently Dr. Chapman has not arrived at this as yet.

The chapters VIII. to XV. describe the various methods of treatment of the disease, and they form the most important part of the book. E. KLEIN

Seaweeds, Shells, and Fossils. By Peter Gray, A.B.S., and B. B. Woodward. (London: Swan Sonnenschein and Co

THE object of this book is to give to the young English collector a general knowledge how to set about collecting the more common seaweeds, shells, or fossils.

In the first case the subject is dealt with generally, classifying the different seaweeds and stating where each is most likely to be found, and, when found, the best way to press them and get them ready for the cabinet, the most economical way of making or obtaining which is given.

Secondly, shells are dealt with, descriptions and diagrams being added where necessary, together with a table of the more important genera, showing the approximate number of species belonging to each genus, and their distribution.

Thirdly, and lastly, different localities are pointed out where fossils are best found, and the best mode of arranging them in the cabinet. A table of the principal fossiliferous strata arranged in chronological order, with notes on the different formations mentioned in the table, and also of the principal divisions of the animal kingdom, are added to show the order in which the fossils should be arranged. S.

The Modernised "Templeton"; or, "The Practical Mechanic's Companion." By William Templeton. Revised and Modernised by Walter S. Hutton, C.E. (London: Crosby Lockwood and Co., 1886.)

TEMPLETON'S "Mechanic's Workshop Companion" is a work familiar to most mechanics and draughtsmen, having been considered for the last quarter of a century a useful book of reference by all connected with the management of engineering workshops and kindred trades. Books of this description require revising very often, and considering the enormous development of the mechanical sciences during the last few years no one will wonder on hearing that even "Templeton" has to be modernised to keep pace with the times.

The reviser tells us that he has endeavoured to follow as far as possible the lines of the original work, at the same time bringing all the information up to date. Much new matter has been added, giving information on air, gas, water, and steam; methods of testing steam-engines and boilers; turbines and other water motors; the strength and weights of material; and miscellaneous information too numerous to give in detail.

The work has for a frontispiece an illustration of the fine compound locomotive "The Marchioness of Stafford," designed by Mr. F. W. Webb, the able locomotive superintendent of the London and North-Western Railway. On seeing this we are at once led to imagine that at last we have found a book giving recent data on locomotive engineering, and likely to fill a want seriously felt by those who study that most interesting branch of mechanical engineering. We are told to "see p. 360," to which we turn hoping to find a section devoted to locomotive work, having Mr. Webb's fine engine as an example of the latest advance. We find a third of a page giving the bare dimensions of the compound. Even the index makes matters no better, for the book contains no locomotive data whatever! Considering the thousands of mechanics engaged in this class of work, this is a great pity, and should be remedied in a future edition.

An excellent abstract is given of the results of experiments on riveted joints, with special reference to practical work, by Prof. Alexander B. W. Kennedy. This is most interesting and useful, and will well repay careful study by those connected with the manufacture of soft steel boilers and bridges.

The book contains all the usual tables, embracing every subject likely to be required by the intelligent mechanic or draughtsman, including extensive practical rules and data Instruction is also given in the rudiments of arithmetic, algebra, and trigonometry. N. J. L.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Foreign Fishery Boards

IN reference to recent statements in NATURE on this subject, it will interest your readers to know that in Italy the Government has constituted a Fishery Board, which, my friend Prof. Giglioli, of Florence, tells me, is actively employed in advising the executive and in inquiring into the grievances and difficulties of fishermen, and the suggestions for improvement of fisheries; it has also recently, at the expense of the Government, taken practical measures in the stocking of lakes with fish, and in the cultivation of sea-fish. This Commission is a branch of the "Ministry of Agriculture, Industry, and Commerce," which corresponds to our Board of Trade. *The members of the Fishery Commission, with the exception of the first three named below, are exclusively scientific men.* They are as follows:—The Permanent Under-Secretary of State for Agriculture; the Permanent Under-Secretary of State for Commerce; a distinguished lawyer; M. Minni, of Venice; Dr. Kenier, of Chioggia (representing the fishermen of this island); M. Friedlander, of Comacchio (specially acquainted with the peculiar fish-culture of this district); Prof. Giglioli, Florence: Prof. Targioni-Tozzetti, Florence; Prof. Costa, Naples; Prof. de Vincentis, Taranto; Prof. Canestrini, Padua; Prof. Pavesi, Pavia; Prof. Issel, Genoa.

The Commission meets from time to time in Rome. The questions submitted to it are brought forward and referred separately to one or two members, who are requested to draw up a report on the particular subject thus referred. The report may take several months, and involve experiment or research, or it may be a simple matter. The report when presented is discussed by the whole Commission. The conclusions and recommendations which it embodies are modified by vote of the majority, and it is obvious from the constitution of the Board that the scientific experts have the voting strength.

The members of the Board or Commission are paid travelling

expenses and 25 francs a day each during its sessions in Rome, or other fixed place of meeting.

The constitution of this Board is admirable, since it secures a fair representation of the leading scientific men of Italy. The Italian Government does not, it seems, refer such questions exclusively to one individual, but endeavours to obtain a consensus of the scientific opinion of the country.

Hôtel de la Ville, Florence E. RAY LANKESTER

Fabry's Comet and Barnard's Comet

NOT having seen any mention of the rapid apparent growth of the tail of Fabry's comet, probably some of your readers are not aware to how great a length it extended. On April 26 occurred the first fine night after a very unusual series of overcast ones, and about 14h. G.M.T. I was surprised to see the tail reaching up to, or at least to within 1° of, δ Cassiopeiæ, a distance of 38° from the place given in the ephemeris for the nucleus, which was far below the horizon; and the tail would doubtless have been visible to a greater distance but for the brightness of the Milky Way. The following night, about 10h., it reached at least up to the Cluster in Perseus, a distance also of 38° from the predicted position of the nucleus; it was very narrow both nights. The next night, which was pretty fine, I failed to find any trace of the tail.

The principal tail of Barnard's comet is also very narrow: on May 1 its length was 4½°, as seen with a pair of field-glasses. With the telescope this comet had also a faint tail *nf*, about 16′ long, making an angle of 65° or 70° with the other.

Sunderland, May 7 T. W. BACKHOUSE

"Pumice on the Cornish Coast"

STEAMER-CINDERS, similar to those referred to by Mr. Whitaker in NATURE for April 29 (p. 604), occur frequently on the Falmouth beaches; but as there seemed to me little probability of their being mistaken for pumice, I did not refer to the matter in my communication to your columns (April 15, p. 559).

Mr. Murray tells me that the pumice I found is felspathic, and that from its form and diminished buoyancy it had evidently been a long time in the water. The fragment was sent by him to Mr. Whitaker, who at once recognised its true character and its distinction from the steamer-cinders observed by him on the Suffolk coast, one of which he sent to Mr. Murray to satisfy him as to their very evident source. THE VELOCITY OF LIGHT

I.

[A reinvestigation of this important constant has recently been published by Prof. Newcomb. Before we state his methods and results we think it well to reproduce the following admirable historical notice with which his monograph commences.—ED.]

WHEN it became clearly understood that vision was not an immediate perception of objects by the eye, but was produced by the passage of an entity called light from the object to the eye, the question of the time which might possibly be required for this passage became one of interest to physical investigators. The first proposal for an experimental investigation of this question is due to Galileo.[1] He suggested that two observers, each holding a lantern, should be stationed at a distance apart, in sight of each other. Each should be supplied with a screen, by which he could, in a moment, cover or uncover his lantern. One observer should then uncover his lantern and the other uncover the other the moment he perceived the light from the first lantern. The interval which elapsed after the first uncovered his light, until he perceived the light of the second, would be the interval required for the light to go and come, plus the time required for the second observer to perceive the light and make the required movement. This experiment was tried by the Florentine Academy, and of course resulted in a conclusion that the time required was insensible, since we now know that it was far below any interval that could have been detected by so rude a method.

It is, however, interesting to notice that, rude though this experiment was, the principle on which it was based is the same which underlies one of the most celebrated methods used in recent times for the attainment of the same object. Two very simple improvements which we might have imagined the Academicians to make in their experiments are these:—

Firstly, to dispense with the second observer, and in his place to erect a mirror, in which the first observer could see the image of his own lantern by reflection. The time required for the second observer to perceive the light and uncover his lantern would then have been eliminated from the problem. The interval sought would have been that between the moment at which the observer uncovered his lamp and the moment at which he perceived the reflection.

Secondly, to use the same screen with which he uncovered his own lamp, to cut off the returning ray from the distant mirror, and thus obviate the necessity of an uncertain estimate of the interval between his muscular effort in removing the screen and his perception of the return flash of light. If the image was perceived before he could cover his own eye with the screen removed from the lamp, it would show that the interval of passage was less than the time required to make a motion with the screen. This interval might have been reduced almost indefinitely by having both lines of sight as near together as possible.

Had these improvements been made, the Academicians would have had, in principle, Fizeau's method of measuring the velocity of light by the toothed wheel, a tooth being represented by the screens. To realise the principle more fully, the two lines of sight should have been rendered absolutely coincident by reflection through a telescope. It does not, however, appear that any effort to put the question to a severer test was made until the subject was approached from a different point of view. It was probably considered that the passage was absolutely instantaneous, or, at least, that the velocity was above all powers of measurement.

The subject was next approached from the astronomical side. In 1676 Roemer made his celebrated communication to the French Academy, claiming that observation of the eclipses of the first satellite of Jupiter did really prove that light required time to pass through the celestial spaces.[1] He found 11m. to be the time required for light to pass over a distance equal to the radius of the earth's orbit. Dominique Cassini, while admitting that the hypothesis of Roemer explained the observed inequality, contested its right to reception as an established theory, on the ground that the observed inequality might be a real one in the motion of the satellite itself.[2]

Continued observation showed that the time assigned by Roemer for the passage of light between the earth and sun, or "the light equation" as it is briefly called, was somewhat too great. In 1809 it was fixed by Delambre at 493·2s., from an immense number of observations of eclipses of Jupiter's satellites during the previous 150 years. This number has been received as a definitive result with a degree of confidence not at all warranted. In 1875, Glasenapp, then of Pulkowa, from a discussion of all available eclipses of Jupiter's first satellite between 1848 and 1870, showed that results between 496s. and 501s. could be obtained from different classes of these observations by different hypotheses.[3]

[1] Poggendorff, *Geschichte der Physik*, p. 402, where reference is made to he *Saggi* of the Florentine Academy.

[1] *Paris Memoirs*, tome i. p. 212, and tome x. p. 575.

[2] *Ibid.* tome viii. p. 47. Poggendorff (*Geschichte der Physik*, p. 656) quotes Maraldi as also contesting Roemer's explanation on the ground that a similar inequality should be found depending on the position of Jupiter in his orbit. The ground here taken was quite correct, the only fallacy being the assumption that such an inequality did not exist.

[3] This paper of Glasenapp's was published only in the Russian language as an inaugural dissertation, and in consequence has never become generally known

As not a trace of Delambre's investigation remains in print, and probably not in manuscript, it is impossible to subject it to any discussion.[1]

The discovery of aberration by Bradley afforded an independent and yet more accurate method of determining the light equation. We call to mind that the latter constant, and that of aberration, are not to be regarded as independent of each other, but only as two entirely distinct expressions of the same result. The constant of aberration gives a relation between the velocity of light and the velocity of the earth in its orbit from which, by a very simple calculation, the time required for light to pass from the sun to the earth may be deduced.

It is remarkable that the early determinations of the constant of aberration agreed with Delambre's determination of the light equation, although we now know they were both in error by an amount far exceeding what was at the time, supposed probable. Struve's value, 20''·445, determined in 1845 from observations with the prime vertical transit of Pulkowa, has been the standard up to the present time. The recent determinations by Nyrén being founded on a much longer series of observations than those made by Struve, and including determinations with several instruments, must be regarded as a standard at present. His result is :—[2]

Definitive value of the constant of aberration = 20''·492 ± 0''·006.

At the time Struve's result was published there was an apparent difference of 1 per cent. between its value and that of the light equation determined by Delambre. The question then naturally arose whether the light equation, deduced on the hypothesis that the tangent of the angle of the constant of aberration was the ratio of the velocity of the earth in its orbit to the velocity of light, might not need correction or modification. This question cannot yet be considered as definitely settled, since the modifications or corrections might arise from a variety of causes. One of these causes is connected with a very delicate question in the theory of the luminiferous medium; a question which can be most clearly understood when placed in the following form :—It is a result of optical principles that a ray falling perpendicularly upon the bounding surface of a refracting medium retains its direction unaltered. Now, if this surface is carried along by the motion of the earth, and the light comes from a star, and it is desired that this surface shall be so directed that there shall be no refraction, must it be placed perpendicular to the *true* direction of the star as freed from aberration, or to its *apparent* direction as affected by aberration? The difference of the two directions may exceed 20'', and since the index of refraction of glass exceeds 1·5, there will be a difference of more than 10'' in the direction of the refracted ray, according as we adopt one or the other hypothesis. Assuming that the standard direction would be perpendicular to the true or absolute direction of the star, it is easily shown that the constant of aberration determined in the usual way would be too large by a quantity depending on the ratio of the thickness of the objective to the focal length of the telescope. In an ordinary telescope the difference would be nearly one-hundredth of the total value of the aberration, and would, therefore, closely correspond to the discrepancy between Delambre's result from the satellites of Jupiter and the modern determinations of the constant of aberration. The question of this particular cause was set at rest by Airy's experiments with a telescope filled with water, which showed that the result was independent of the thickness of the objective, and, therefore, that the apparent direction of the star was that on which refraction depended.

If, in accordance with the undulatory theory of light, we suppose the hypothetical entity called "the luminiferous medium" to be a substance, each part of which has its own definite and fixed location in space, then we must conceive that another unknown quantity may enter into the problem, namely, the motion of the heavenly bodies through this medium. We have relative motions in the solar system, exceeding 50 kilometres per second, and possibly greater relative motions among the stars. Now it is clear that the heavenly bodies cannot all be at rest relative to the medium, but must move through it with velocities at least of the order of 50 kilometres per second, and possibly greater without limit, since it is conceivable that the whole visible universe might be moving in a common direction relative to the medium.

It is easily seen that if we suppose the velocity of the earth, through the medium, to have a small ratio, a, to the velocity of light, then the observed constant of aberration may be altered by an amount found by multiplying its value by a quantity of the order of magnitude of a. This alteration would be entirely insensible if the earth does not move through the medium with any greater velocity than it does around the sun, since the value would then be only $\frac{1}{10000}$. It is remarkable that so far as yet investigated every optical effect arising from such a motion, which could be measured on the surface of the earth, is of the order of magnitude of the square of a. Thus, no phenomenon has yet been discovered which can be traced to the motion in question.

Assuming that there is no general motion of the solar system through the ether of a higher order of magnitude than that of the relative motions of the fixed stars to each other, and that the ordinary theory of aberration is correct, there will be three constants between which a relation exists, such that when any two are found the third can be determined. These constants are :—

1. The distance of the sun in terrestrial units of measure;

2. The velocity of light in units of the same measure; and

3. The constant of aberration, or, which is supposed to be equivalent, the light equation.

Until our own time the first and third constants were used to determine the second. From the fact that light required about 500 seconds to traverse the distance from the sun to the earth, and that the distance of the sun was, as supposed, 95,000,000 of miles, it was concluded that light moved 190,000 miles per second. The hopelessness of measuring such a velocity by any means at the command of physicists was such that we find no serious attempt in this direction between the date of the futile effort of the Florentine Academy, and that of the researches of Wheatstone, Arago, Fizeau, and Foucault nearly two centuries later. One of the most curious features presented by the history of the subject is that two entirely distinct methods, resting on different principles, were investigated and put into operation almost simultaneously. The revolving mirror of Wheatstone, and its application to determine the duration of the electric spark and the velocity of electricity, come first in the order of time. But, before this ingenious instrument had been applied to the actual measurement of the velocity of light, Fizeau had invented his toothed wheel, by which the same object was attained

Fizeau's paper on the subject was presented to the Academy of Sciences on July 23, 1849.[1] We have already shown that his method and that of Galileo rest fundamentally upon the same principle. The arrangement of his apparatus was substantially as follows :—

A telescope was fixed upon a house at Surêsne pointing to the hill Montmartre. On this hill was a second fixed telescope looking directly into the first, the distance between them being about 8633 metres. In the focus of this second telescope was fixed a small reflector, so that

[1] The author could find no remains of this investigation among Delambre's papers at the Paris Observatory.

[2] *Mémoires de l'Académie Impériale des Sciences de St. Pétersbourg*, vii. série, tome xxxi. No. 9.

[1] *Comptes rendus*, vol. xxix. 1849, p. 90.

a beam of light from the first would be reflected directly back to it. By means of a transparent glass, fixed in the eye-piece at an angle of 45°, a beam of light was sent from the first telescope to the second, and, on its return through a total distance of 17 kilometres, could be seen as a star by an eye looking through the first. Alongside the eye-piece of the latter a revolving wheel, with 720 teeth cut upon its circumference, was fixed in such a way that the beam of light both in going and coming had to pass between the teeth. When the wheel was set so that the tooth was in the focus, the beam would be entirely cut off in its passage through the telescope. Changing the position of the wheel through half the space between the middles of two consecutive teeth, the light would go and come freely between the teeth. When the wheel was set in revolution a succession of flashes would be sent out. If, on the return of each flash, a tooth was interposed, it would be invisible to the eye looking through the telescope. Fizeau found that with a velocity of 12·6 turns per second each flash which went out was on its return cut off by the advancing tooth. With a velocity twice as great as this it was seen on its return through the opening next following that through which it went. With three times this velocity it was caught on the second tooth following, and so on.[1]

This experiment of Fizeau was soon followed by the application of the revolving mirror of Sir Charles Wheatstone. Shortly after measuring the duration of the electric spark this investigator called attention to the fact that the same system could be applied to determine the velocity of light, and especially to compare the velocities through air and through water. In 1838 the subject was taken up by Arago, who took pains to demonstrate that it was possible, by the use of the revolving mirror, to decide between the theory of emission and that of undulations by determining the relative velocities in air and in a refracting medium.[2]

The difficulties in the way of securing the necessary velocities of the mirror and of arranging the apparatus were such that Arago never personally succeeded in carrying out his experiments. This seems to have been done almost simultaneously by Foucault and Fizeau about the beginning of 1850. Both experimenters seem to have proceeded substantially on the same principle and to have reached the same result, namely, that the motion of light through water was slower than through air in the inverse proportion of the indices of refraction of the two media.[3]

An important and most necessary modification of Arago's plan was made by these experimenters. As originally proposed, the plan was to send an instantaneous flash of light through water and through the air, and to receive it on the revolving mirror and determine the relative deviations in the positions of the images produced by the two rays. This system would, however, be inapplicable to the measurement of the actual time of transmission, owing to the impossibility of making any comparison between the time at which the flash was transmitted, and that at which it was received on the mirror. This circumstance would, indeed, have rendered the actual realisation of Arago's project nearly impossible for the reason that the flashes of light, seen through the water, would have reached the mirror at every point of its revolution; and only an exceedingly small fraction of them could have been reflected to the eye of the observer.

This difficulty was speedily overcome by Foucault and Fizeau by a most ingenious arrangement, of equal importance with the revolving mirror itself. Instead of sending independent flashes of light to be reflected from the mirror, a continuous beam was first reflected from the revolving mirror itself to a fixed mirror, and returned from the fixed mirror back on its own path to the revolving one. A succession of flashes was thus emitted as it were from the fixed mirror, but their correspondence with a definite position of the revolving mirror was rendered perfect. Moreover, by this means, the image was rendered optically continuous, since a flash was sent through and back with every revolution of the mirror, and after the velocity of the latter exceeded 30 turns per second, the successive flashes presented themselves to the eye as a perfectly continuous image.

It was not until 1862 that this system was put into operation by Foucault for the actual measurement of the velocity of light through the atmosphere. A new interest had in the meantime been added to the problem by the discovery that the long-accepted value of the solar parallax was too small, and that the measurement of the velocity of light afforded a method of fixing the value of that constant. The central idea of the method adopted by Foucault was that already applied in comparing velocities through different media. The element sought is made to depend upon the amount by which the revolving mirror rotates while a flash of light is passing from its surface to the distant reflector, and coming back again. As the details of Foucault's method will be best apprehended by a comparison of them with those adopted in the present investigation, a complete description of his apparatus will here be passed over. It may, however, be remarked, that what he sought to observe was not the simple deviation of a slit, but the deviation of the image of a reticule. The deviation actually measured was 0·7 millimetre, and the system adopted was to determine at what distance, with a definite velocity, this amount of deviation could be obtained. His result for the velocity of light was 298,000 kilometres per second.

The next measures of the element in question were those of Cornu. The method which he adopted was not that of the revolving mirror, but Fizeau's invention of the toothed wheel. His earlier measures, made in 1870, and communicated to the French Academy in 1871, led to a result nearly the same as that of Foucault.[1] This result was, however, not so satisfactory that the author could record it as definitive. He, therefore, in 1874, repeated the determination on a much larger scale and with more perfect apparatus. The distance between the two stations was nearly 23 kilometres, and therefore much greater than any before employed. He was thus enabled to follow the successive appearances and extinctions of the reflected image to the thirtieth order; that is, to make fifteen teeth of his wheel pass before a flash returned from the distant reflector, and to have it stopped by the sixteenth tooth.

This method has a defect, the result of which is evident by an examination of Cornu's numbers. It is that the extinctions and reappearances of the light as the wheel changes its speed are not sudden phenomena, occurring at definite moments, but are so gradual that it is difficult to fix the precise moment at which they occur. Of this defect the able experimenter was fully conscious, and his discussion of the disturbing causes which come into play, and of the amount of error due both to the apparatus, the observer, and to the method of eliminating them, form altogether one of the most exhaustive discussions of a physical problem.[2] But the uncertainties are not of a kind which admit of complete investigation, and it now appears that although his result was far superior in point of accuracy to that of Foucault, it was nevertheless in error by about 0·0015 of its whole amount. It was, in

[1] It is curious that the author's account of this remarkable experiment, which forms an epoch in the history of physical science, is contained within the limits of two pages, and terminates without any definite discussion of the results. It is merely stated that the result is 70,948 leagues of 25 to the degree, but the velocity, in kilometres, which must have been that first obtained, is not given, nor is it stated what length the degree was supposed to have in the computation.

fact, when reduced to a vacuum, 300,400 kilometres per second, while we may now regard it as well established that the true velocity is less than 300,000.

The next determination of the velocity of light was that of Michelson,[1] whose result was 299,910 kilometres per second. His investigation being a part of the first volume of the present series need not be here discussed, but it is worth while to remark that his method seems far superior in reliability to any before applied.

An attempt has been made by Messrs. James Young and George Forbes to improve Fizeau's method, by diminishing the uncertainty arising from the gradual extinction of the visible image.[2] By the method of these experimenters the result depends, not upon the moment when the image disappears, but when two images, side by side, are equal in brightness. This is effected by employing two reflectors, at unequal distances, but nearly in the same line from the telescope, to return the ray. Each reflector then forms its own image in the field of view of the sending telescope. With a regularly increasing velocity of the toothed wheel, each image goes independently through the same periodic series of changes as when only one mirror is used; but owing to the unequal distance the period is not the same. If the speed of the mirror be carried to such a point that the difference of phase in the two images is half a period, then one image will be increasing while the other is diminishing, and the stage at which the two images are equal would appear to admit of fairly accurate determination.

The distant reflectors were separated from the observing telescope by the Firth of Clyde. The distances were respectively 16,835 feet, and 18,212 feet. A study of the printed descriptions of their experiments gives the impression that the performance of the subsidiary parts of the apparatus was not such as to do justice to the method. The resulting velocity of light was 301,382 kilometres per second, and the difference between the extreme results of twelve separate determinations was 4000 kilometres.

The most important result of the work of these gentlemen, could it be accepted, would be the establishment of a difference between the velocities of differently-coloured rays. We may regard it as quite certain, from the absence of any change in the colour of the variable star, β Persei, while it is increasing and diminishing, that the difference between the times required by red and by blue rays to reach us from that star cannot exceed a moderate fraction of one hour. It is quite improbable that its parallax is more than $0''.1$, and therefore probable that its distance is 2,000,000 or more astronomical units. The possible difference between the velocities in question can, therefore, only be a small fraction of the hundred-thousandth part of either of them. No apparatus yet devised would suffice for the measurement of a difference so minute, and we are justified in concluding that the phenomena observed by Messrs. Young and Forbes arose from some other cause than a difference between the velocities of red and blue rays.

The present determination had its origin as far back as 1867. In his "Investigation of the Distance of the Sun," published in that year, the author introduced some remarks upon Foucault's method, and pointed out the importance to the determination of the solar parallax of repeating the determination of Foucault on a much larger scale, with a fixed reflector placed at a distance of three or four kilometres.[3]

From that time forward the subject excited the attention of American physicists, several of whom formed plans, more or less definite, for executing the experiments. As, up to the year 1878, no important steps in this direction had been taken, the author, in April of that year, brought the subject before the National Academy of Sciences, with the view of eliciting from that body an expression of opinion upon the propriety of asking the Government to bear the expenses of the work. The subject was referred to a Select Committee, who, in January, 1879, made a favourable report on the subject, which was communicated to the Secretary of the Navy. On the recommendation of the Secretary, Hon. R. W. Thompson, Congress, in March following, made an appropriation of $5000 for the purpose, and the author was charged by the Department with the duty of carrying out the experiments.

In the meantime it became known that Mr. Michelson had made preparations for repeating Foucault's determination at his own expense, with the desirable improvement of placing the fixed reflector at a considerable distance. But before the reliability of Mr. Michelson's work had been established, the preparations for the present determination had been so far advanced that it was not deemed advisable to make any change in them on account of what Mr. Michelson had done. The ability shown by the latter was, however, such that, at the request of the writer, he was detailed to assist him in carrying out his own experiments, and acted in this capacity until September 1880, when he accepted the Professorship of Physics in the Case Institute, Cleveland, Ohio. After the departure of Mr. Michelson his place was taken by Ensign J. H. L. Holcombe, U.S.N., who assisted in every part of the work to the entire satisfaction of the projector until its close.

PANCLASTITE

DR. SPRENGEL has sent us a reprint of a note sent by him to the *Chemical News* on this subject. After showing that these new explosives, so named by Mr. Turpin, are not original, he continues:—

"The 'beau idéal' of a detonating explosive is a mixture of 8 parts (88.9 per cent.) of liquid oxygen and 1 part (11.1 per cent.) of liquid hydrogen.

"In my paper of 1873 I say, p. 799:—'On referring to the foregoing table the reader will be reminded that peroxide of hydrogen is the highest oxygen compound known, while nitric anhydride is the compound which contains the largest amount of oxygen available for combustion (74 per cent.). But as this compound, as well as the next two, nitric peroxide (69.5 per cent. oxygen) and tetranitromethane (65.3 per cent. oxygen) are: at present: on account of their nature and their difficult preparation, mere chemical curiosities, my attention naturally turned to the fourth, to *nitric acid* (63.5 per cent. oxygen), which is a cheap and common article of commerce.'

"Now, when Mr. Turpin's attention turned to the second oxidiser on my list—to nitric peroxide—he found that this substance does *not corrode* metals, such as iron, copper, and tin under 356° F. (180° C.); and further, that combustible liquids, such as petroleum, carbon bisulphide, and nitro-benzene are readily soluble in nitric peroxide *without* rise of temperature. These are valuable properties, *first noticed by Mr. Turpin.*

"What was formerly a chemical curiosity is now an article of commerce. Nitric peroxide may be bought to-day at eighteenpence the pound, and I see ways and means of producing it a great deal more cheaply. Nitric peroxide is a yellowish liquid, heavier than water (sp. gr. = 1.451), and boils at 71° F. (22° C.), but may be kept like ether or similar volatile liquids. In France it is sent about in tinned-iron cans.

"Taking as a typical example a benzene-mixture—

$$\left.\begin{array}{l} C_6H_6 = 18.4 = \begin{array}{r} 17.0\ C \\ 1.4\ H \end{array} \\ 7\tfrac{1}{2}(NO_2) = \underset{\overline{100.0}}{81.6} = \begin{array}{r} 56.8\ O \\ 24.8\ N \end{array} \end{array}\right\} = \begin{array}{l} 62.6\ CO_2 \\ 12.6\ H_2O \end{array}$$

we see, that the 18·4 parts of benzene require 56·8 parts of oxygen for the oxidation of their carbon and hydrogen to carbonic acid and water. This oxidation or combustion takes place at the moment of explosion at the expense of the 56·8 parts of oxygen, contained in the rest of the mixture—the 81·6 parts of nitric peroxide. No other explosive now in use (including blasting gelatin) contains weight for weight a greater amount of combustible matter, and as an explosion of *these* bodies is simply a sudden combustion, I again beg to draw attention to the fact that the oxygen available for combustion in gun-cotton is most probably not more than 32·3 per cent. and in nitroglycerin 42·3 per cent.,[1] while in this case we have without a doubt 56·8 per cent. Hence no other explosive now in use can rival this and similar mixtures in power, as I published in 1873. They still remain *the most powerful* explosives known.

"It hardly need be said that an explosive of this nature consists of two parts—an oxidising and a combustible agent—and that Mr. Turpin with the same *naïveté* lays claim not only to the first, but also to the latter half of the subject.

"None of my *safety*-explosives are licensed in England, though many of them, when mixed, are much less sensitive to concussion than common gunpowder.

"In April 1884 the French military authorities were busy near Rochefort with shells of the 'système Turpin.' These shells, so my informant said, were made of such a size, and possessed such a prodigious power, that a ship struck by one of them would inevitably be sent to the bottom of the sea, even were she the strongest ironclad afloat. It is devoutly to be hoped that those whose office it is to provide for the defence of the British Navy *will be ready* in the hour of need to serve out shells, filled with an explosive of equal force or better still with something superior, approaching more closely the 'beau idéal.'"

MR. VERBEEK ON THE KRAKATÃO DUST-GLOWS

As it appears from the letter of Mr. Douglas Archibald in NATURE of April 29 (p. 604) that some doubt exists as to the quantity of volcanic dust ejected during the Krakatão eruption in 1883, it may not be inopportune to give an abstract of what Mr. Verbeek—the best authority on the subject—says in the second part of his book. The mistake in the number of cubic kilometres—which Dr. Riggenbach or his critic magnified from 18 into 150—may possibly have arisen from the comparison Mr. Verbeek draws between the quantity of volcanic substances ejected by the Tambora in 1815 and that ejected by Krakatão.

Junghuhn estimated the quantity of ashes ejected by the Tambora in Sumbawa at 318 cubic kilometres, but Mr. Verbeek reduces it by calculation to about 150, though he adds that the data are insufficient to form a really correct estimate. It is certain, however, that the quantity was considerably larger than that ejected by Krakatão. To calculate this quantity Mr. Verbeek made observations everywhere on the islands and along the coasts of the Straits of Sunda; while the thickness of the ashes which fell into the sea was computed according to the difference in the depths of the sea before and after the eruption, a difference which greatly varies, and amounts in some places to 40 metres, if not more. Wherever some doubt exists for want of previous accurate deep-sea soundings, Mr. Verbeek gives the lowest figures. These observations are all illustrated by maps. Mr. Verbeek estimates the quantity of ejected material which fell round the volcano at 18 cubic kilometres at least. The possible outside margin would, however, not exceed 3 cubic kilometres. Of this quantity, two-thirds, or 12 cubic kilometres, lies within a circle with a radius of 15 kilometres drawn round Krakatão, one-third, or 6 kilometres, outside it. Of the finer ashes a large quantity were already, during the first three days, blown into the sea, as appeared from observations made on ships; and Mr. Verbeek assumes that considerably less than 1 cubic kilometre remained floating in the upper regions of the atmosphere. This quantity would correspond to a layer of 0·002 millimetre thickness divided over the whole surface of the earth, or of 0·004 millimetre over the temperate zones only.

Such an infinitesimally thin layer could hardly have been the principal cause of the atmospheric phenomena. They must be accounted for in a great measure by the large volume of aqueous vapour ejected by Krakatão, the amount of which lies, unfortunately, beyond all calculation. We have to deal with two distinct phenomena, as Prof. Michie Smith also has shown by the two different spectra, and these phenomena had different causes: thus, the blue and green tints of sun and moon, which were specially observed during the first month after the eruption, and only in places close to the equator, must be principally ascribed to the *solid* particles in the volcanic ash-cloud, as various observations have shown that these are the main cause of the special absorption of the rays of light by which the sun appeared blue and green; the aqueous vapour may have increased the phenomenon, for it is known that the sun can look bluish through mist. It cannot be said to be a proof to the contrary that Mr. Lockyer saw the sun green through the steam which escaped from the funnel of a steamer, for probably a quantity of ash and soot-particles escaped from the funnel at the same time, and it is possible that the sun appeared green from that very fact. The steam was thus in the identical condition of our volcanic cloud. It was only in the beginning after the eruption, before the ashes had spread very far, and when, therefore, their density was greater, that they were able within a limited space to give green tints to the sun. This phenomenon ceased when the ashes were dispersed further round the globe—in the northern hemisphere by the south-west, in the southern hemisphere by the north-west winds—and when probably also a portion of them fell gradually on the earth.

The crimson after-glows which soon followed the eruption were observed *at the same time* over a much larger area than that within which the blue and green sun was seen at successive periods, and they are believed by Mr. Verbeek to have been caused mainly by the masses of aqueous vapour thrown out by Krakatão, and which formed the greater part of the volcanic cloud. This vapour, after condensing and freezing in the higher and colder regions of the atmosphere, produced the remarkably beautiful sunsets, while the ashes may have intensified the phenomenon, besides serving as a centre of condensation for the vapour. The real cause of the crimson glows was therefore probably the same as that of the evening red, their intensity being a consequence of the extraordinary quantity of vapour in the upper regions emitted by Krakatão.

THE PARIETAL EYE OF HATTERIA

Some little time ago, whilst engaged in work upon *Hatteria punctata*, I found a curious sense-organ embedded in the substance occupying the parietal foramen, but was unable at the time to examine the specimen further; Prof. Moseley has kindly directed my attention to a short paper published in the *Zoologischer Anzeiger*

[1] Of these, by the bye, only 38·8 per cent. can be utilised for want of fuel, as pointed out by me in my patent of 1871, and verified four years later by the force of Nobel's blasting gelatin, in which the excess of 3·52 per cent. oxygen is utilised by the dissolved gun-cotton, an explosive too rich in carbon. See Abbot's table, p. 17, in "The Hell-Gate Explosion near New York and so-called 'Rackarock,' with a few words on so-called 'Panclastite,'" by H. Sprengel. London: E. and F. N. Spon, 1886.

for March 29, 1886, by Von Henri W. de Graaf, "Zur Anatomie und Entwickelung der Epiphyse bie Amphibien und Reptilien," wherein are described briefly (1) the development of the epiphysis, and (2) the structure of this part in the adult animal in certain amphibia and reptiles. An examination by means of sections at once revealed the fact that in Hatteria the epiphysis becomes modified in a manner more interesting than that found by Von Graaf to obtain in *Anguis fragilis*—the most modified form described by him.

The epiphysis apparently arises as a hollow outgrowth from the roof of the third ventricle (region of thalamencephalon), and in both amphibia and reptilia becomes divided into two parts—a proximal one remaining in connection with the brain, and a distal bladder-shaped structure—the two becoming in most cases completely separated from each other. In *Anguis fragilis* Von Graaf finds that the distal part loses all connection with the brain, and develops into a structure resembling a highly organised invertebrate eye with, however, the important and curious exception that no nerve is present.

In Hatteria a still more interesting modification takes place, the distal portion being, as in Anguis, modified to form an eye; but this, unlike that in the latter, is provided with a well-marked nerve.

Fig. 1 shows the structure of the eye. The whole is enclosed in a capsule of connective tissue (C); anteriorly a lens (L) is present, composed of cells whose nuclei are very distinct. The lens forms the anterior boundary of a vesicle, the walls of which are formed

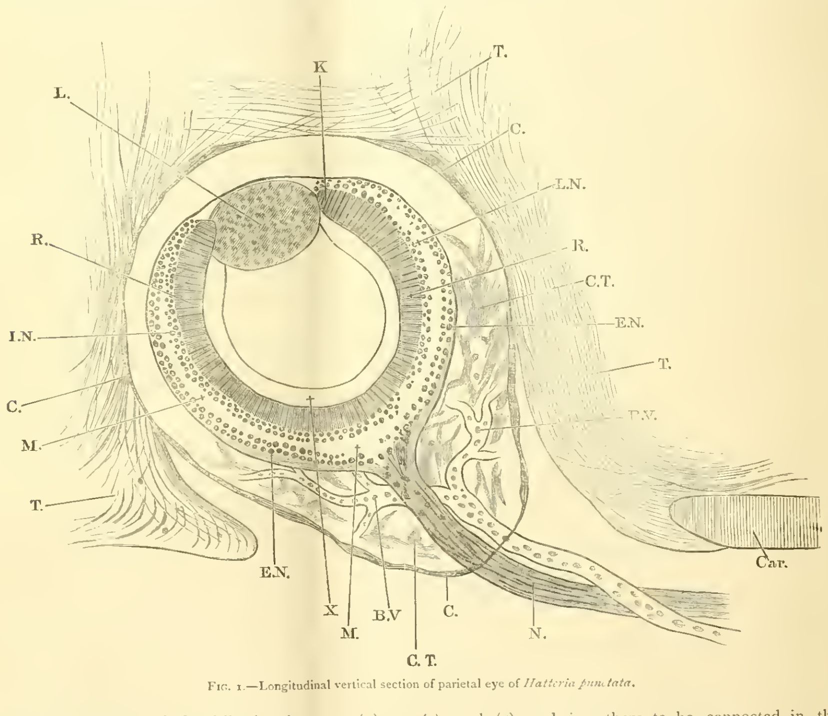

FIG. 1.—Longitudinal vertical section of parietal eye of *Hatteria punctata*.

from within outwards of the following layers:—(1) a layer which is not well marked (X), and which may possibly be due to the shrinkage and clinging to the walls of the contents of the vesicle, fluid in life; (2) a layer of rods (R) embedded in dark brown pigment, the pigment being specially developed anteriorly at the part indicated by the letter K; (3) a double or even triple row (I N) of nuclei; (4) a clear layer (M) which scarcely takes stain, and may be called the molecular; and (5) an outer layer (E N) of nuclei two or three rows deep.

This structure will, so far, be seen to correspond closely with that of Anguis.

Posteriorly a nerve enters the eye, the fibres spreading round behind the vesicle; the rods may be observed giving off processes from their external ends, which in some cases appear to pass right through the layers (3), (4), and (5), and in others to be connected in their passage with the nuclei of these layers.

However, I hope in a very short time to publish a detailed account of the histological structure of the organ.

The capsule containing the eye is filled posteriorly with connective tissue (C T), in which breaks up and ramifies a blood-vessel which enters along with the nerve (B V).

Fig. 2 represents somewhat diagrammatically a section transverse to the parietal foramen, showing that the eye is single and lies exactly in the median line. A depression of the skin of the head occurs immediately over the parietal foramen, but does not lead down into this, which is filled up by a plug of connective tissue (Fig. 1, T, Fig. 2, P T), specially dense (D T) around the eye capsule. The nerve

is single, and leads downwards and backwards in the median line, being enveloped in the tissue passing from the foramen directly to the roof of the thalamencephalon.

I have not yet actually traced the nerve itself into the brain, but it is difficult to imagine that it can possibly arise as a branch from a cranial nerve, being *single* and *medianly placed*, and, as just said, enveloped in the material running directly to the roof of the brain from the foramen.

There can be little doubt that it represents the stalk connecting the distal with the proximal outgrowth from the roof of the thalamencephalon, this part having apparently disappeared in other reptiles and amphibia (so far as is yet known).

This being the case it is extremely interesting to observe that another instance will be added to that of the optic nerves in which an, at first, hollow outgrowth from the brain becomes solid and transformed into a nerve, and further that the latter, as in the former case, is connected with an organ of vision.

Though it is difficult to imagine what can be the use of the organ in its present state, seeing it is deeply embedded in connective tissue—so deeply as almost to

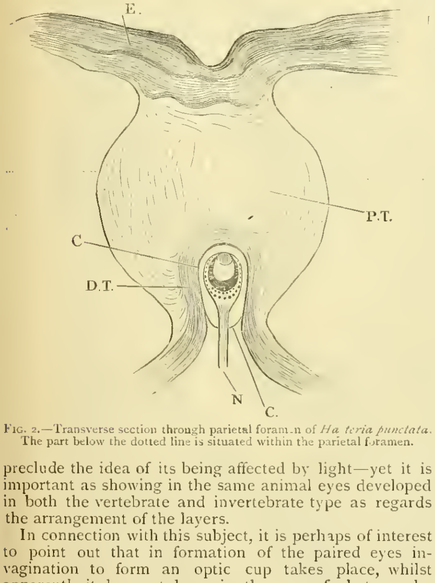

FIG. 2.—Transverse section through parietal foramen of *Hatteria punctata*. The part below the dotted line is situated within the parietal foramen.

preclude the idea of its being affected by light—yet it is important as showing in the same animal eyes developed in both the vertebrate and invertebrate type as regards the arrangement of the layers.

In connection with this subject, it is perhaps of interest to point out that in formation of the paired eyes invagination to form an optic cup takes place, whilst apparently it does not do so in the case of what may be called the *parietal eye*. A little consideration shows that the relative position of the rods depends entirely upon this invagination. In both cases they are formed upon the inner surface of the wall in the position corresponding to the epithelium of the neural canal: but in the one instance they are, by decay of the outer wall of the invaginated cup, placed apparently on the outside of the optic vesicle; whilst in the other instance they are formed in a similar position, but, as no invagination takes place and subsequent decay of one wall, they line the cavity of the vesicle. According to this we must suppose that the part of the wall where the lens is present has either disappeared or become modified into this.

We may further observe that in both types of eye the nerve enters into connection with the elements on the surface opposite to that on which the rods are developed.

In conclusion my thanks are due to Prof. Moseley for his kindness in drawing my attention to the subject, and to Mr. E. B. Poulton, of Keble College, Oxford, who kindly placed two specimens of Hatteria at my disposal, and to Mr. Beddard, of the Zoological Society, for the use of another specimen. W. BALDWIN SPENCER

Anatomical Department, University Museum, Oxford

NOTE.—Since writing the above I have found the eye present in several other lizards, notably in Iguana, *Chameleo vulgaris* and *Lacerta ocellata*, and have traced the nerve into the proximal part of the epiphysis.

ASTRONOMICAL PHOTOGRAPHY[1]

SOME attempts made last year at photographing the heavens by means of an instrument quite rudimentary having yielded good results, the director of the Paris Observatory gave orders for the construction of a special apparatus, the design of which is shown in the accompanying figure (Fig. 1). The mechanical part has been executed in a highly remarkable manner by our accomplished artist, M. Gautier; the objective is our own production.

This new instrument is composed of two telescopes in juxtaposition inclosed in a single metallic tube in the form of a parallelopiped, and separated from each other along their whole length by a narrow partition.

One of the object-glasses, with an aperture of 0·24 m. and a focal length of 3·60 m., is intended for eye observation, and serves as a pointer. The other, with an aperture of 0·34 m. and a focus of 3·43 m., is achromatised for the chemical rays, and serves the purpose of photography. The optical axes of these two objectives being parallel, every star kept in the centre of the field of the eye-piece belonging to the first telescope produces its impression in the centre of the sensitive plate of the photographic apparatus.

The equatorial is mounted in the form called English, that is to say, the centre of the tube rests always in the polar axis of the instrument. This arrangement allows of a star being followed from its rising to its setting without involving the necessity of bringing the instrument back to the vicinity of the meridian. Like a common equatorial it is furnished with hour circle and circle of declination, and with a clock movement keeping the apparatus in operation for three hours without fresh remounting. There are, moreover, independent very slow movements, whereby the axis of the telescope can be kept on a fixed point in the heavens, notwithstanding some slight irregularity in the movement of the clockwork, the orientation of the telescope, or the variations of atmospheric refraction.

The photographic objective—the largest ever yet produced—is formed according to a simple achromatic system, and, though of an extremely short focal length, is able, without the use of any diaphragm, exactly to cover the very considerable field of 3° diameter.

Although but very recently mounted, this apparatus has already availed for the performance of numerous tasks. On star photographs it is possible to distinguish traces of stars of the 15th magnitude, too feebly marked, however, to bear transference on paper. The stars of the 14th magnitude are reproduced with a diameter of 1/40 of a millimetre.

It is obvious that such small points might be liable to be confounded with the impurities of the sensitive coating if the precaution is not taken to multiply the stationary points. Each star is formed by a group of three points constituting an equilateral triangle, each side of which is no more than 1/12 of a millimetre. To the naked eye these three points appear to merge into one, but on examining them with the aid of a somewhat

[1] From an article by the Brothers Henry in *La Nature*.

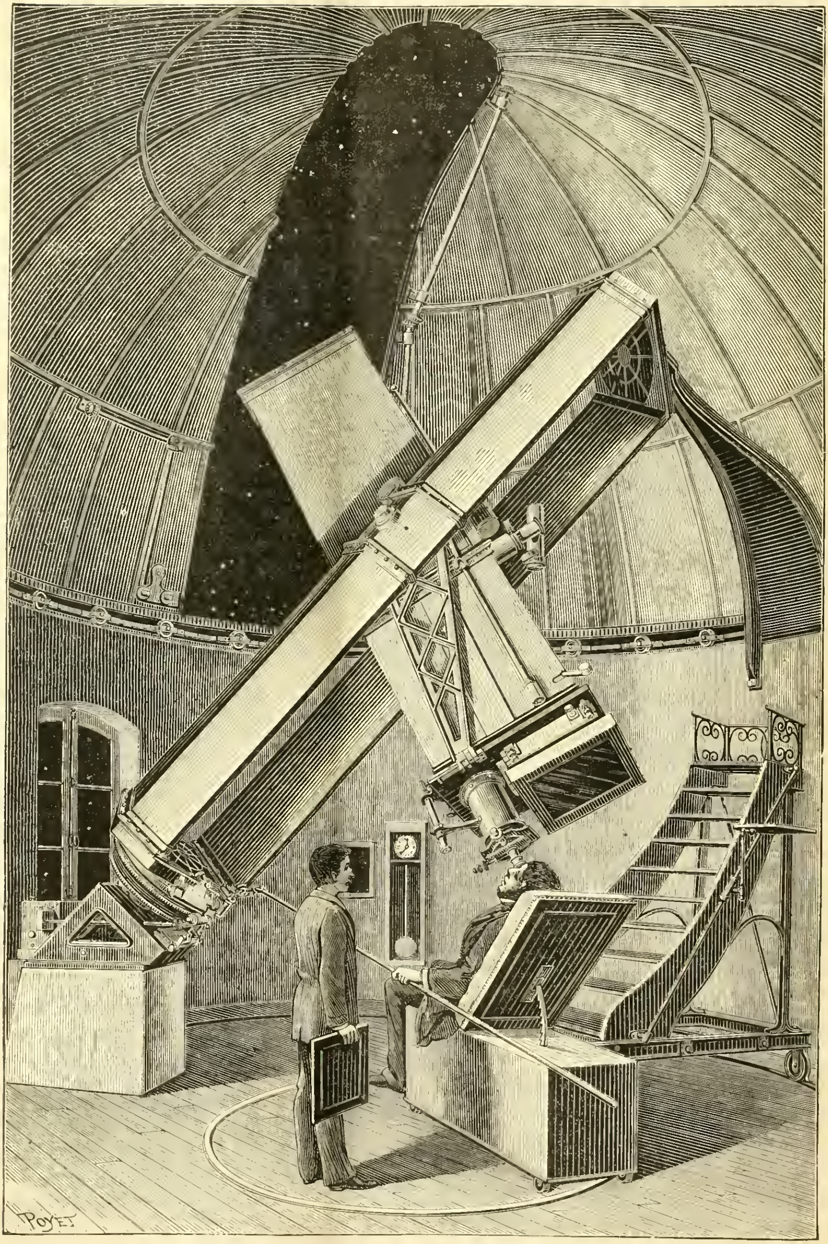

FIG. 1.—Parallactic apparatus newly established at the Paris Observatory for celestial photography.

powerful lens the three points come out distinctly, and it is then an easy task to eliminate all that does not belong to the heavens.

The construction of such a map, obtained by the apparatus as above described in three hours, would assuredly have demanded several months of assiduous labour by the ordinary processes.

The following is the time of exposure requisite to obtain the image of the stars.[1]

Magnitude		h.	m.	s.
1	...	0	0	0·005
2	...	0	0	0·013
3	...	0	0	0·03
4	...	0	0	0·08
5	...	0	0	0·2
6	The extreme limit of magnitude of stars visible to the naked eye	0	0	0·5
7	...	0	0	1·3
8	...	0	0	3
9	...	0	0	8
10	...	0	0	20
11	Mean magnitude of the asteroids	0	0	50
12	...	0	2	0
13	...	0	5	0
14	...	0	13	0
15, 16	The last of the stars visible with the aid of the great instruments	1	23	0

All the above figures represent a minimum. To secure good reproductions on paper the time of exposure would have to be increased threefold.

The above table shows that the time of exposure required in taking a star of the first, and that in taking a star of the last magnitude differ from each other as 1 : 1,000,000. (The relation adopted between the brightnesses of two consecutive magnitudes is 2·542.)

Outside the construction of celestial maps, another field of study of great importance now created by photography may be cited, the discovery, namely, of the asteroids. The little stars fixing themselves on the plate as so many mathematical points, so to say, the planets are distinguished therefrom, each by a little line perfectly defined indicating its proper movement in amount and direction during the time of exposure of the apparatus. It is in this way we have already succeeded in obtaining the trace of a small planet of the 11th magnitude which by a small line extremely well defined gave account of its march among the fixed stars.

It will even be possible to study the movement of the satellites round their planet, and perhaps discover new ones.

The study of the double and multiple stars will be greatly facilitated, and photography will be equally available in the investigation of the parallaxes.

Finally, photometry must be adduced as one of the branches of astronomy which will now be able to collect very valuable information through the utilisation of photography.

In conclusion, it is worth while remarking how this fresh step in advance has sensibly enlarged the scope of man's vision. In consequence of it we can now obtain the image of a star, which instruments of the same opening as those employed by photography would never of themselves have elicited out of their invisibility.

PAUL ET PROSPER HENRY

NOTES

THE first *soirée* of the Royal Society this season took place last night. A large number of Fellows and visitors were present, and many objects of interest were exhibited.

THE visitation of the Royal Observatory by the Board of Visitors is fixed this year for June 5.

[1] For these results we have made use of the gelatino-bromide plates of Monckhoven.

THE Royal Irish Academy is celebrating the centenary of its foundation this week.

DR. GILL, Her Majesty's Astronomer at the Cape, has been elected Corresponding Member of the Imperial Academy of Sciences of St. Petersburg.

THE fifty-seventh anniversary meeting of the Zoological Society was held on Thursday week. The chair was taken by Prof. Flower, LL.D., F.R.S., the President. The report of the Council on the proceedings of the Society during the year was read by Mr. P. L. Sclater, F.R.S., Secretary of the Society. It stated that the number of Fellows on December 31, 1885, was 3193, showing a decrease of 62 as compared with the corresponding period in 1884. The total receipts for 1885 had amounted to 25,809*l.* 10*s.* 1*d.*, being a decrease of 3129*l.* as compared with the previous year. This decrease was mainly due to the falling off in the receipts under the head of admissions to Gardens, and in the amounts received for admission and composition fees from newly elected Fellows. The ordinary expenditure for 1885 had been 24,593*l.* 11*s.* 8*d.*, against 26,539*l.* 4*s.* 1*d.* for 1884. Besides that, an extraordinary expenditure of 491*l.* 0*s.* 6*d.* had been incurred, which brought up the total expenditure for the year to 25,084*l.* 12*s.* 2*d.* The visitors to the Society's Gardens during the year 1885 had been 659,896, against 745,460 in 1884. The Davis Lectures on zoological subjects, having been well attended during the past year, would be continued during the present season, beginning with a lecture on "Pigs and their Allies," by Prof. Flower, LL.D., F.R.S., on Thursday, June 3, at 5 p.m. The number of animals in the Society's collection on December 31 last was 2551, of which 756 were mammals, 1366 birds, and 429 reptiles. Among the additions made during the past year 21 were specially commented upon as of remarkable interest, and in most cases new to the Society's collection. About 36 species of mammals, 15 of birds, and 4 of reptiles had bred in the Society's Gardens during the summer of 1885. The report concluded with a long list of the donors and their various donations to the menagerie during the past year.

WITH regard to the recent explosion of the 43-ton gun, it is fortunate that it has happened without loss of life. Competent authorities, as seen from Col. A. Moncrieff's letter (which we reproduce from the *Times*) show that it could. How long are our gun factories to go on making guns condemned by easily-understood scientific principles? "Col. Maitland's interesting paper read at the Royal United Service Institution on June 20, 1884," Col. Moncrieff writes, "published the process adopted at Woolwich in settling the types of the new steel breech-loading ordnance for the British service, as well as the proportions of the new guns on these types then in process of manufacture. Mr. W. Anderson's investigations, published in a lecture read before the Society of Arts on January 29, 1885, and also commented upon in the *Engineer* of February 6, 1885, clearly demonstrated that these guns were deficient in strength in front of the trunnions. It is a remarkable fact that several of the guns have now burst at the point and in the manner which could have been predicted by any one consulting Mr. Anderson's demonstrated results. As the subject is of vital importance to the country, it would seem wise either to refute Mr. Anderson or accept his method and consult him; his valuable service in having discovered the prevailing error and worked out this most difficult problem is too little known; it would thus be utilised and acknowledged to the advantage of the service. By treating a gun as a heat-engine and accounting for every part of the energy generated by the explosion of the powder, he has, in a scientific and complete manner, proved that the metal crusher gauges from which the accepted curve of pressure is obtained are not to be relied on.

The form of the guns is adapted to the curve of pressure; that curve, as shown by Col. Maitland at the Royal United Service Institution, is wrong; the maximum pressure which is near the breech is known, but with the slow-burning powder in a long gun the total pressure, and the maximum pressure at any point of the bore, has never been accurately determined. If Mr. Anderson's conclusions carefully arrived at by calculation are correct, these guns are out of proportion between the trunnions and the muzzle, where the bursts have all taken place. Another branch of the same subject is the measurement of the energy of recoil, of much importance in designing disappearing carriages. In this branch, I can answer for it, that Mr. Anderson's conclusions tally with the practical result—a satisfactory proof of their correctness. His discovery is of great practical value in making gun-carriages of all descriptions, and has changed, once and for all, the previously accepted formulæ for the force of recoil given in the text-books, which often led to costly mistakes in construction. Mr. Anderson has been trying, since the publication of his lecture at the Society of Arts, to induce the Government to test the correctness of his views by means of the Sebert velocimeter, but without success. It must be admitted that in determining so important a matter, one on which the efficiency of our ships and a large national expenditure depends, it should be the first desire of every one to secure without delay the highest scientific and practical experience within reach, and to consult men who have devoted special study and research to the subject."

On April 30 there took place in Paris, at the Ministry of Public Instruction, a meeting of French astronomers. M. Faye was in the chair. It was decided unanimously to build three photographing telescopes. One of these is destined for the Algiers Observatory. The destination of the others will be determined upon when finished. The construction will take eighteen months.

M. Janssen has terminated the installation of the tubes for analysing the influence of the atmosphere on spectroscopic analysis, absorbing power, &c. Their length is 100 metres, and they can be filled with gas under a pressure of 100 atmospheres. The light is supplied by a battery of 60 Bunsen elements. Experiments are conducted on nitrogen, oxygen, common air, &c.

Herr Paul von Ritter, who died at Basle, has left to the University of Jena a sum of 300,000 marks, to be employed for the furtherance of zoological studies.

Canada is nearly the only important British colony without its Government Botanic Garden; the identity of its flora with that of the Northern United States rendering such an establishment of much less value than in most of our colonial possessions. But for some years past leading Canadians interested in horticulture have been exerting themselves for the establishment of a Botanic Garden at Montreal. Through the co-operation of the authorities of McGill College and the Council of the Montreal Horticultural Society, this object is now secured, and the "First Annual Report" of the "Montreal Botanic Garden" is issued. The Garden is not yet in existence; but a very favourable site of seventy-five acres has been secured in Mount Royal Park, a varied piece of ground admirably adapted for the purpose, on the slope of the beautiful mountain overlooking the city, from which it derives its name. An Act of Incorporation for the "Montreal Botanic Garden Association" has been obtained, wherein the objects of the corporation are stated to be "By the medium of a Botanic Garden and other accessories, to promote research in forestry and economic botany, and advance the interests of technical and general botanical knowledge." Among the means contemplated in the future for carrying out these objects we are glad to see the establishment of courses of lectures on special subjects and a laboratory for special research. We wish every success to the new Association, which solicits contributions in trees, shrubs, seeds, and publications.

At the last general meeting of the Folk-Lore Society, Capt. Temple read a paper on the science of folk-lore. At the conclusion he referred to terminology. Folk-lore, he said, is a fine English compound, but there is a sad want of an alternative, if only for the sake of useful and necessary derivatives. Folk-lorist and folk-loric are not pleasant forms, but students have been driven to use both. He suggests some classically-formed synonym, such as *demology*, *demosophy*, or *demonocy*—the last for choice—capable of easy development into passable derivatives, as being of practical use. Dogma has been appropriated already, or *dogmology* might, he thinks, answer, and *demodogmology* is too long. *Dokeology* and *dokesiology*, as the study of fanciful opinions, are also suggested.

In a recent article in *La Nature* M. Martel refers to a discovery which he has made in the prehistoric caves in Lozère. For fifteen years past Dr. Prunières has prosecuted his investigations into the dolmens and neolithic grottos of the gorges of the Tarn, and has obtained some curious results on the fusion of a race of the age of polished stones and of an invading race of the Bronze Age. Last year in the cave of Nabrigas, M. Martel found in immediate contact with the remains of at least two skeletons of the *Ursus spelæus*, or great Quaternary bear, nine fragments of human skulls, of which one left superior maxillary had three teeth, and a piece of rough pottery, not turned in a lathe. The question whether, in the Stone Age, man, the contemporary of the reindeer and the great bear, was acquainted with the use of pottery is much debated, eminent names being found supporting the negative as well as the positive. But (continues M. Martel) the curious point about the present find is that fifty years ago, before the birth of "pre-history," when the existence of even Quaternary man was contested, M. Joly found in this very cave of Nabrigas a fragment of a large vessel in contact with the skull of a fossil bear. M. Martel is strongly of opinion that the usual theory of the fortuitous contact of these objects does not apply here; there is no trace of any disturbance, nor are any other neolithic objects found, the skull is in its natural position,—for these and other reasons he is persuaded that fossil man of the palæolithic age was acquainted with the potter's art.

The fish-hatching season at South Kensington, accounts of which we have published from time to time, is now drawing to a close, although there are still half a million fry on view at the Exhibition which have not yet absorbed their *umbilical sac*. The various species of fish bred have been presented by the National Fish Culture Association to public waters in the vicinity of London and in the country, whilst the Fishery of the Association has been well stocked with fry.

The Thames Angling Preservation Society, which is ever ready to secure fresh supplies of fish for the Thames, have lately netted one of the ponds in Kew Gardens for this purpose.

During the present week large consignments of fish have arrived at the aquarium of the Colonial and Indian Exhibition from the south coast and North Sea. The latest arrivals consist of cod, lings, haddocks, crustaceans of various species, grey mullet, bream, and Salmonidæ. A large Ascension turtle has also arrived in the tropical department, measuring 4½ feet by 3 feet. Considering the protracted period it was out of the water during transit, its condition on being placed in the Chelonian tank did not evidence the slightest signs of diminished vitality, which is another proof of the hardihood and tenacity of life possessed by this species. The turtle tank now contains twenty large specimens of the green and hawksbill kind, all of which seem in good health notwithstanding the artificial existence to

which they are subjected. In contiguity to the tank is a miniature beach whereon the turtle rest when out of water. A consignment of turtle eggs is expected this week, which will be laid out in the hatchery on arrival for the purpose of incubation. Some West Indian tortoises have just arrived, together with a selection of snakes and lizards, which form interesting exhibits. In consequence of the inability of the Royal Commissioners to obtain Indian and Colonial fishes, the National Fish Culture Association have taken the matter into their own hands, and have made arrangements with the Zoological Society in Calcutta and other bodies for supplies of tropical and other piscatorial specimens, so that the aquarium will be supplemented with many rare and important specimens.

MR. OTIS T. MASON's account of the valuable Guesne collection of antiquities in Point-à-Pitre, Guadaloupe, which appeared in the Smithsonian Report for 1884, has recently been issued in separate form. The collection originated with M. Mathieu Guesne, whose series of Carib stone implements attracted considerable attention at the Paris Exhibition of 1867. Since then it has been continued, and all but completed, by the son, M. Louis Guesne, who has devoted nearly twenty years of assiduous labour to the task of rescuing from destruction all existing relics of the ancient Carib race in the Island of Guadaloupe. He has also applied his artistic skill to the illustration of these objects, filling two large albums with aquarelles in natural size and colour of all the types in his museum. From these sources Mr. Mason has mainly compiled the present account, which is enriched with no less than 215 carefully prepared woodcuts of the Point-à-Pitre collection, and of a few others introduced for the purpose of comparison, and to supply omissions in West Indian archæology. The collection includes roughly-worked stones, indicating an industry in its infancy; and others so perfectly finished that it would be difficult to improve upon them either in design or workmanship. But all alike belong to what would be called the Neolithic period in Europe; all the stone implements are polished, and there is not a single object of this class formed solely by being chipped. In fact, the volcanic materials of which they are made cannot be worked by chipping, like flint, quartz, or obsidian. Some, especially, of the axes are so small that they seem to belong to a race of pigmies, while others are so large and heavy that they suggest a generation of Titans rather than of human beings. Besides the movable objects, mention is made of enormous stones carved with strange designs resembling those described by Mr. Im Thurn in British Guiana, some so high up as to be almost out of reach, others close to the ground or buried under the surface. Similar inscribed stones occur in the beds of rivers in the Island of St. Vincent, the last refuge of the Caribs in the West Indies.

HERR SCHÖYEN, in a paper recently reprinted from the *Transactions* of the Scientific Society of Christiania, describes a form of disease affecting the roots of growing barley, through which the farmers in Norway have of late years been suffering extensive loss. Contrary to the common opinion that the ravages due to this blight—which is popularly known as "Krog," crook, from the form of the deposits—were produced by an insect, Herr Schöyen maintains that this special barley-pest is a microscopic round worm, of the genus Tylenchus. After describing the appearance and character of the parasitic germs, which are deposited at the extremities of the roots, where their presence speedily manifests itself by the withering and death of the stalk before the grain can be set, he draws attention to the fact that similar deposits have been noticed on the roots of *Elymus arenaria*, the bind-grass so frequent on the Scotch, as well as the Norwegian, coasts. This observation derives special practical importance from the circumstance that at Lom, in Norway, where the barley crops have suffered most severely from the "Krog," the affected fields are in close vicinity to extensive tracts of *Elymus arenaria*. He proposes to continue his observations next summer with special reference to this point, but in the meanwhile he recommends as the only remedy available for the present that barley should not be re-sown on ground where the disease had manifested itself in the preceding season, nor in any locality where Elymus abounds. He finds that the bladder-like egg-cases of *Tylenchus hordei* can be thoroughly desiccated without destroying the inclosed worms.

SOME interesting statistics of the Japanese press have lately been published in the *Oesterreichische Monatsschrift für den Orient*, in which the newspapers and periodicals of Japan are arranged according to the subjects with which they deal. It appears that 37 publications are devoted to matters connected with education, and that these have a total circulation of 42,649 per month. There are 7 medical papers, with a monthly circulation of 13,514; 9 relating to sanitary matters, with a circulation of 8195; 2 on forestry; and 2 on pharmacy. There are 7 devoted to various branches of science, with a circulation of 2528; but to these must be added 29 engaged in popularising science, with a total circulation of 70,666.

THE additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus leucoprymnus* ♀) from Ceylon, presented by Mrs. Larkins; a Brazilian Tree Porcupine (*Sphingurus prehensilis*) from Brazil, presented by Mr. J. E. Wolfe; two Sloth Bears (*Melursus ursinus* ♂ ♀) from India, presented by Mr. H. Mainwaring; a Burmese Squirrel (*Sciurus atrodorsalis*) from Burmah, presented by Mr. C. Crofton Black; a West Indian Agouti (*Dasyprocta cristata*) from West Indies, presented by Dr. A. Boon, F.R.C.S.; an Orange-thighed Falcon (*Falco fusco-cærulescens*) from Chili, presented by Capt. W. M. F. Castle, R.N.; five Senegal Parrots (*Pœocephalus senegalus*) from West Africa, presented by Mr. R. B. Sheridan; two Kestrels (*Tinnunculus alaudarius*), British, presented by Mr. J. S. Malcolm; a Wedge-tailed Eagle (*Aquila audax*) from Australia, presented by Mr. R. B. Colvin; a Tuberculated Iguana (*Iguana tuberculata*) from West Indies, presented by Mr. D. Morris; seven European Tree Frogs (*Hyla arborea*), European, presented by Mr. Thompson Hudson; a Californian Quail (*Callipepla californica*) from California, a Herring Gull (*Larus argentatus*), British, presented by Miss Hodge; a Two-banded Monitor (*Varanus salvator*), two Rat Snakes (*Ptyas mucosa*), an Indian Cobra (*Naia tripudians*) from Ceylon, presented by Mr. Carl Hagenbeck; a Moorish Toad (*Bufo mauritanica*) from Italy, a Green Toad (*Bufo viridis*) from Malta, presented by Mr. Alban Doran, F.R.C.S.; two Greek Tortoises (*Testudo græca*), European, presented by Admiral Mellersh; two Common Vipers (*Vipera berus*), British, presented by Mrs. Mowatt; a Small Hill-Mynah (*Gracula religiosa*), from Southern India, deposited; a Hog Deer (*Cervus porcinus*), seven Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE FLEXURE OF MERIDIAN INSTRUMENTS.—In a paper which forms Appendix III. to the "Washington Observations" for 1882, Prof. Harkness has made an exhaustive discussion of the subject of flexure, and the means available for eliminating its effects from star-places. He discusses separately the flexure of transit instruments and of vertical circles. The former are divided into two classes, according as their telescopes are straight or bent, but it is in the latter form that the effects of flexure are by far the greatest, the flexure-coefficients being in some instances as much as 0·55s. Prof. Harkness shows that the effect of flexure cannot be satisfactorily eliminated from the concluded right ascension of a star by simply taking the mean of the four results obtained by observing it directly and by reflec-

tion with the clamp of the instrument both west and east. It is better in his opinion to determine for each instrument the necessary corrections to be applied by means of the methods and formulæ explained in this paper.

In discussing the flexure of vertical circles Prof. Harkness compares Repsold's method of eliminating the flexure, by interchanging the object and eye-end of the telescope, with Bessel's method of attaining the same result by observing a star both directly and by reflection with the clamp successively west and east, demonstrating the superiority of the latter method, which appears to be the most satisfactory procedure hitherto devised for freeing an observed declination from the effect of flexure.

Prof. Harkness shows that when there are terms in the flexure depending on multiples of the zenith distance, they cannot in general be completely eliminated, and therefore that star-places derived from observations made with a single instrument are likely to be affected by systematic errors, which will appear when the work of different instruments is compared together. The detection and elimination of such errors can probably, Prof. Harkness thinks, be greatly facilitated by the use of equal altitude instruments of the zenith telescope class, which are so remarkably free from systematic errors.

THE SPECTRUM OF FABRY'S COMET.—M. Trépied having frequently observed the spectrum of this comet since April 7, gives (*Comptes rendus*, vol. cii., No. 18) the following account of it. The three usual cometary bands were seen, and as the brightness of the spectrum allowed a fairly narrow slit, 0·2 mm., to be used, the coincidence of these bands with those of the hydrocarbon spectrum could be very satisfactorily verified. Besides these bands there was also a continuous spectrum, but the remarkable feature of the case was that although the nucleus, which was very distinct and of a truly stellar appearance, appeared very bright as compared with the neighbouring portions of the coma, the band spectrum given by these latter and by the tail was much more brilliant than the continuous spectrum of the nucleus. This circumstance, which was also observed by MM. Thollon and Perrotin at Nice, had been remarked by M. Trépied in Encke's comet last year. He is therefore led to conclude that there is a predominance of gaseous elements in both these comets, and that, further, the relative brilliance of the nucleus of a comet is not necessarily in accord with the degree of condensation of the cometary matter.

On April 14 the bright bands could be easily detected in the spectrum of the tail to a distance of 20′ from the nucleus. The total length of the tail was then more than 3°.

TWO NEW COMETS.—Mr. W. H. Brooks, Red House Observatory, Phelps, New York, discovered two new comets in the last week of April, the first on April 27, the second on April 30. The former is described by M. Bigourdan as being on May 1 a round nebulous object, about 2′ in diameter, brighter towards the centre, but without a nucleus. The existence of a very faint nucleus was, however, suspected on the following night. On May 6 Lieut.-Col. Tupman estimated the comet as being of the 8th magnitude. Dr. H. Kreutz has computed the following elements and ephemeris for it:—

T = 1886 June 6·9585 Berlin M.T.

$$\left.\begin{aligned} \omega &= 202^\circ\ 55'\!\cdot\!68 \\ ☊ &= 191\ 48\!\cdot\!58 \\ i &= 87\ 33\!\cdot\!03 \end{aligned}\right\}\text{ Mean Eq. 1886·0}$$

$\log q$ = 9·40752

Ephemeris for Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log Δ	Brightness
May 13	2 9 38	51 43·7 N.	0·1062	2·2
17	2 30 25	47 52·2	0996	2·9

29	3 26 26	32 15·3 N.	0·0794	10·0

The brightness on April 29 is taken as unity.

The second comet is described (*Astr. Nach.* No. 2728) by the Baron von Engelhardt as being very bright on May 3, although the evening was misty. The comet was visible in a bright field, and showed a circular nucleus, from whence proceeded a brighter offshoot, 2′ in length, in the direction of the axis of the tail. The tail was 8′ in length and very bright, narrow at first, but broadening by degrees, and curved with the convex side towards the north. A secondary tail, 6′ in length, faint, and bending towards the south, forked off from the principal tail about 6′ from the nucleus. The following elements and ephemeris are by Dr. E. Lamp:—

T = 1886 May 4·13040 Berlin M.T.

$$\left.\begin{aligned} \omega &= 37^\circ\ 50'\!\cdot\!15 \\ ☊ &= 287\ 22\!\cdot\!88 \\ i &= 99\ 47\!\cdot\!53 \end{aligned}\right\}\text{ Mean Eq. 1886·0.}$$

$\log q$ = 9·92518

Error of middle place ($O - C$).

$d\lambda = +\ 0''\!\cdot\!19 \qquad d\beta = -\ 0''\!\cdot\!02$

GEOGRAPHICAL NOTES

AMONGST the members of the mission proceeding from India to Tibet, under the charge of Mr. Colman Macaulay, are Col. Tanner, surveyor, Dr. Oldham, geologist, and Dr. Cunningham, naturalist. The expedition will leave Darjeeling about the end of the present month, and, marching through independent Sikkim, will cross the Jalepla Pass into Tibet. Its destination is Lhassa, the capital. Once only has this city been visited by an Englishman, Thomas Manning, and practically the whole route lies through a *terra incognita*. As Mr. Macaulay bears letters from the Chinese authorities, for which he made a special journey to Pekin last year, it is not anticipated that he will meet with any obstacles on his way to, or during his stay on, "the roof of the world." The three scientific members of his mission will find abundance of work to do, and the news of the progress of the expedition may be looked for with interest.

THE new number of the *Journal* of the Royal Asiatic Society (vol. xviii., part 2) contains an interesting article by Mr. Morison, of Tiflis, on the geographical distribution of Turki languages. The following is a summary. Dividing Turki into five sub-branches—Turki proper, Nogai, Uigur, Khirghiz, and Yakut—he states that the various subdivisions of, first, Turki proper, are spoken by the ruling class of the Ottoman Empire and the inhabitants of Asia Minor, in the Governments of Nijni Novgorod, Kasan, Simbirsk, Viatka, and Orenburg, in Trans-Caucasia, and North-Western Persia ; the Nogai in Bessarabia, the Crimea, Cis-Caucasia, the Volga Delta, North-Eastern Daghestan, Terek Valley, the north-western shore of the Caspian, the Governments of Kasan and Simbirsk, Astrakan, Orenburg, and Ufa ; the Uigur in Yarkhand and Chinese Tartary, the country of the Tekke, Zarafshan Valley, and generally in Central Turkestan, in the Khanate and Desert of Khiva and south of the Aral Sea, and in Kuldja ; the Kirghiz from the Volga to the confines of Manchuria, but most compact in South-Western Siberia ; and the Yakut in North-Eastern Siberia and on the northern slopes of Mount Sayan. Broadly speaking, says Mr. Morison, the Ugro-Altaic languages, of which Turki is one, are spoken over a region extending through more than 100° of longitude, from the shores of the Adriatic to the Great Wall of China and the plateau of Tibet, and through 35° of latitude, from the frozen steppes of Samoyede and Yakut to the plains of Northern Persia and the head-waters of the Indus. The Turki alone, according to the figures given, is spoken, in one or other of its various forms, by more than 20,000,000 of people.

THE *Proceedings* of the Royal Geographical Society for May contains a paper by Mr. Carles on his recent journeys in Corea, accompanied by a very useful map of the peninsula. Some account of these journeys has already appeared in Parliamentary Blue-Books, but much is added in the present paper. The writer refers to the many different types found amongst the Coreans of the present day ; the facial characteristics of the people greatly resemble those of the Manchus, but Jews, Japanese, and Caucasians appear to be universally represented. There is also a curious reference to evidence of some forms of religion other than those imported from China in the *miriok*, or half-length human figures carved in stone. Mr. Needham also contributes an account of an excursion to the Abor Hills from Sadiya in Upper Assam.

BARON MIKLUHO-MACLAY has just returned to Odessa from his journey to New Guinea, which has lasted two years. He has brought a large collection of rare fishes, lizards, snakes, insects, and so on, packed in twenty-two boxes.

ANOTHER Russian traveller, M. Goudatti, the Secretary of the Moscow Society of Friends of Natural Science, who has also just returned from his journey to the north of Siberia, gives a curious account of his failure to accomplish his purpose. The Ostiaks and Samoyedes took him for a Government official on a recruiting mission, especially when he attempted to measure their heads, and took notes in his note-book. Finally the book was stolen, and all the results of his efforts lost.

HERR RADDE, who had started in January last with a scientific expedition from Tiflis to the Transcaspian region, writes from Askabad lately that this spring was very unfavourable for his researches, being three to four months later than usual. Therefore up to the middle of April he had not succeeded in collecting more than 35 species of plants and about 150 birds. Amongst these latter there is an interesting novelty, the *Picus sindiacus*, a pretty bird living in the high shrubs of *Tamarix*. The explorer intends to proceed during the present month to the mountain region between the Murghab and Tejen, and to return to Askabad through Sarakhs.

THE May number of the *Scottish Geographical Magazine* has an interesting article by Mr. Tripp on the physical configuration and rainfall of South Africa, with notes on its geology, diamond and coal-fields, and forests. The paper is accompanied by two maps showing contours and mean annual rainfall. A note by M. Dingelstedt on geographical education in the schools of the Caucasus shows that in Russia primary instruction in geography is as defective as in England. It is not made attractive, the writer complains ; it only taxes the memory ; the text-books are written to match, and few teachers are equal to the task of interesting their pupils in the subject. There are some interesting notes on the place-names of Kinross-shire by Mr. Liddall, and on the seaboard of Aberdeenshire, by Mr. Ferguson. The geographical notes are particularly copious and comprehensive.

THE current number (Bd. xiii. No. 4) of the *Verhandlungen* of the Berlin Geographical Society contains only one paper—a lecture by Dr. Naumann on the Japanese Islands and their inhabitants. The *Zeitschrift* of the same Society (Bd. xxi. Heft 2) is mainly occupied by a paper of Dr. Schweinfurth's on a journey which be made in the "region of depression" around Fayoum at the commencement of the present year. It is accompanied by a map, and fills 53 of the 66 pages forming the number. There is a short paper of great interest on the Maori population of New Zealand, based on the last census of that colony. The writer (who does not give his name) discusses the causes of the dying out of the race, and also the attitude of the Colonial Government towards the Maories. There is a note from Prof. Kunze on the climatology of South America, and, lastly, a long list of barometrical observations by Lieut. François in the Kassai region.

THE SUN AND STARS[1]

VI.

Summary of Results

IN what has gone before we have found that the prominences, and the spots, have special spectra unlike the ordinary spectrum of the sun, and unlike the spectra of the chemical elements.

Further, we know that when we proceed outwards to the spectra of the inner and outer corona we find ourselves very little better off, for, with the exception of hydrogen, there is no substance which is perfectly familiar to us ; and finally, when we come to study the association of phenomena on the sun, we find that, exactly while the spots and prominences give us the greatest divergences from terrestrial conditions, solar facts indicate that these phenomena are allied in the most close and obviously important manner. We must henceforth consider that the spots and the metallic prominences and the faculæ represent different indications of the same solar action.

Now, to continue this part of the inquiry is fundamental for us. It is almost impossible to see a large spot at the edge of the sun, which is the place for observing it best, without finding this downrush towards the photosphere answered, so to speak, by an uprush from below the photosphere—without finding this downrush of cool, absorbing, dark-and-widened-line-producing material, re-echoed by an uprush of bright-lined substance.

There is one word which expresses, as well as anything I can think of, the impression which is made on one by the phenomena. There is a *splash*. Imagine an enormous cauldron of liquid iron, as hot as you like. Play some water into it from a hose ; there will be a splash. The water, of course,

[1] A Course of Lectures to Working Men delivered by J. Norman Lockyer, F.R.S., at the Museum of Practical Geology. Revised from shorthand notes. Continued from vol. xxxiii. p. 543.

would be very violently heated; we probably might get some explosions, and as the result of these explosions some liquid iron might be carried with the liquid water which has entered into the liquid iron here and there. The metallic prominences always are close to spots. They almost always follow them like the faculæ. I might have told you, in fact, while talking of this, that of 1100 cases in which spots and faculæ have been observed together, in 581 the faculæ were to the left of, or behind, the spots. Only in 45 were they on the right or in front. We shall see the importance of this by and by.

If we can invariably, as we do, associate the descent of material which, though we do not see it falling, we know is there, and that it is relatively cool—*if we can associate these descending absorption-phenomena with a subsequent upward splash*, we must look upon the most intensely active prominences as being return upward currents, though in some cases it may be that what we see as the spectrum of a prominence at the limb is, in part, that of the vapour descending to form a spot.

The Sunspot Period

The next thing we have to do is to discuss the periodicity of the various solar phenomena, to which attention has already been directed. It is worth while again to refer to the two very interesting and important curves in which Prof. Spörer has recorded the results of his own observations.

When the spots are at their fewest the small number we do see begin in a high latitude N. or S., from 30° to 35°; as the spots increase in number and activity we get, at the maximum sunspot period, the chief appearances observed in middle latitudes—about lat. 18°; and then the mean latitude of the spot zone still gets lower and lower, until at the next sunspot minimum we get two systems of spots—one of them, lowest in latitude (about 8° N. and S.), ending the first cycle, and another in latitude 30° beginning the next. These are the salient features of the periodicity to which we have now to confine our attention.

It has been previously pointed out that there are other periodicities with a much shorter period than eleven years; certain changes are seen to occur among the quiet prominences. Still this is the main periodicity with which we are familiar on the sun; and what we have now to do is to endeavour to see whether we can follow all the phenomena in their changes.

The two last maxima occurred in the year 1871 and eleven years afterwards in 1882 and some time after that year. At those times we got the greatest amount of spotted area and the most intense solar action. Similarly the two last periods of minimum activity were in 1867 and eleven years afterwards in 1878.

Now, in order to investigate this question in the most satisfactory manner, I think, and I doubt not you will agree with me, that we should begin with the simplest case.

The Minimum

The simplest case is evidently that in which the sun is quietest. At first sight it may appear a little hazardous to talk about the sun being at its quietest; but we know, as a matter of fact, that there is a tremendous difference at different times in the solar activity along the lines to which reference has been made.

But in the light of what has already been stated let us suppose the sun at its quietest, what phenomena shall we see?

There will be very few of the ordinary tree-like prominences anywhere on the sun, and especially will there be a dearth of them near the poles and near the equator.

There will be faculæ, but the faculæ will be dim; they will not present the bright appearance they generally do, and what there are will be mostly confined to the regions of latitude comprised between 20° N. and 20° S.

If by means of a spectroscope we attempt to determine the chemical materials in the chromosphere, we shall find just those five lines only to which we have referred in the spectrum as ordinarily visible—that is, four lines of hydrogen, and one line named D_3.

Practically speaking, there will be no spots visible upon the disk; the disk will appear to be perfectly pure, almost equally illuminated throughout, barring always the darkening towards the limb.

As there are no spots, or only very small ones in high latitudes, there will be, we can easily understand from what has gone before, no metallic prominences whatever. The spectroscope searching right round the limb of the sun will gather no indications of violent action—no region giving us many lines—nothing but that simple spectrum of hydrogen to which I have already referred.

What, then, is the appearance put on by the corona if we can manage to get an idea of a corona at the minimum sunspot period? We see, the moment that question is suggested, how excessively important it is that all eclipses should be observed, whether they occur at the maximum or the minimum of the solar activity. Fortunately, since the year 1860 these wonderful phenomena have been observed with more or less diligence; and since the year 1871—that is fifteen years ago now—with few exceptions, not only have those eclipses been observed by the eye with great care, but photographs of the extremest value have been obtained.

Unfortunately, that first minimum to which I have referred—the minimum in 1867—took place practically before the general introduction of this perfect photographic record of eclipses; and there is no good photograph extant of that eclipse; but fortunately, good photographs were secured of the eclipse of 1878. You can imagine our American cousins did not let an opportunity like that of advancing knowledge slip; and the result was that the whole land along the line of totality bristled with telescopes and cameras, which did their work in an admirable way. So that in the eclipse of 1878 we did get a photographic record, that is to say, an absolutely trustworthy record, of the appearance presented by the sun's corona at the minimum sunspot period. If it were not so, I should have hesitated to show you the drawing made in 1867; but I think you will say, when I show you these records together, that the drawing in 1867 is so like the photograph taken in 1878 that on that ground alone it is worthy of extreme confidence; and if we can accord such confidence to it, we arrive at the very important conclusion that at two different sunspot minima the appearances presented by the corona were very much alike indeed.

At the minimum period the chief feature is a tremendous extension of the corona in the direction of the solar equator. At both the poles, north and south, there is a wonderful curving

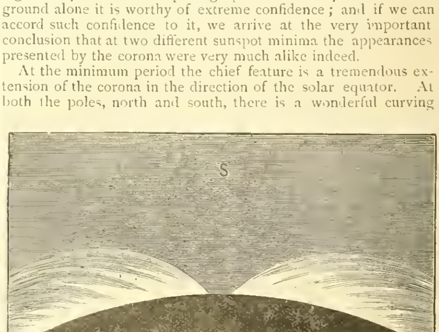

Fig. 10.—Outcurvings at the solar poles (1878).

right and left; this outcurving having been one of the most exquisite things which it is possible to imagine.

There is further evidence indicating that the equatorial extension on the photograph may only after all have been a part of a much more extended phenomenon, one going to almost incredible distances—considering it as a solar atmosphere—from the sun itself.

It has already been stated that at that eclipse one observer took extreme precautions to guard his eyes from being fatigued by the light of the inner corona, which sometimes is so bright that observers have mistaken it for the limb of the sun itself. What this gentleman, Prof. Newcomb did, was to erect a screen which covered the moon and a space 12′ high round it. The result was, that as soon as he took his station at the commencement of totality, he saw a tremendous extension of the sun's equator on both sides the dark moon, the extension being greater than that recorded in the photograph. It does not follow that the photograph gives us the totality of the extension; it may be that the extended portions may have been so delicately illuminated, that they would not impress their image on the photographic plate in the time during which that plate was exposed, or that the light itself is poor in blue rays. So considerable was this extension, amounting to six or seven diameters of the dark moon, which practically may be taken to be the same as that of the sun behind it, that Prof. Newcomb had at once suggested to him the zodiacal light. It happened that while this eclipse was

being observed by Prof. Newcomb and myself—we were practically close together at a height of 7000 feet—other observers were viewing the eclipse from Pike's Peak, some few hundred miles away, at a height of 13,000 feet. You can imagine the purity of the air at that height; there was not too much of it—so little in fact that some observers had to go down. These saw the corona very well indeed; and one or two observers, without taking the precaution of putting up a screen, saw an extension almost comparable with that recorded by Prof. Newcomb.

That, then, we must take to be the undoubted result arrived at during the eclipse of 1878, which happened at the last sunspot minimum. We have a tremendous equatorial extension; that is the great feature, and it is proved by photographs.

The drawing made in 1867 gives us the same result. We again get the equatorial extension east and west, and the wonderful outcurving right and left from the sun's poles.

Hence, then, we must associate a corona of that kind, *i.e.* having a considerable equatorial extension, with that quiet condition of things at the sun, during which metallic prominences, ordinary prominences, faculæ, and spots show a minimum of activity.

You will remember that we saw from the sunspot curve that from minimum to maximum it mounts rapidly, reminding one of a steep cliff. We have in fact only three years from minimum to maximum, while we have eight years from maximum to minimum.

The Approach to Maximum

We have then next to consider the solar condition between minimum and maximum. We must suppose ourselves to be half-way up the steep part of the curve that connects the maximum with the minimum. In this case we find a greater activity in all directions. The hydrogen—or the quiet—prominences are more numerous. The faculæ are brighter. If we now examine the chromosphere we find hydrogen and D^3 are not the only constituents—we get those other short lines added of which Prof. Tacchini has given us such a valuable list, among them chiefly being those three lines of magnesium which are designated b^1, b^2, b^4. That is the chemical difference between the chromosphere of the sun at this time, and the first period at which we considered it. The spots also are more numerous, and what spots there are we have in a lower latitude; instead of making their appearance in latitude 35°, they will be nearer latitude 25°—they will have come down 10° from the solar poles towards the equator. These more numerous spots will also be constantly accompanied by metallic prominences, and the number of lines visible as bright lines in these prominences we shall find increasing as the observations are made month after month.

How about the outer atmosphere of the sun? Well, remarkable changes begin to take place in it too. In considering the minimum corona I said nothing about its spectrum, for the reason that I wished that wonderful bilateral and symmetrical and simple form to rivet the attention. But now it is right that I should say that one of the chief changes between this corona as the maximum is approached and the minimum one is not only the change of form to which I shall have to draw attention, but a change in the spectrum. At the minimum sunspot period the corona gives exactly, or very nearly exactly, the same spectrum as the lime-light or a jet of gas—we get very nearly a continuous spectrum. The chief difference between the spectrum of the corona, then, and the spectrum of the gas jet, is that in this continuous corona spectrum certain dark lines will be seen, but no very obvious bright lines are there. We therefore have to come to the conclusion that at the minimum the corona is not chiefly gaseous in its spectrum, but that it consists of solid particles to a very large extent; and that these solid particles are not only competent to reflect light, but that they actually do reflect light coming from the lower portions of the sun; and in that way we account for the presence of the Fraunhofer lines.

But when we come to the second period we are now discussing, these change to a very large extent; the spectrum is no longer continuous; bright lines begin to make their appearance, and with this coming-in of bright lines comes in a greater brilliancy.

And then as to the form. The diagram is copied from a drawing taken in the year 1858, at exactly the right period to illustrate any change which may have taken place on the approach to maximum. Unfortunately it is not a photograph. Those who lecture in this theatre twenty or a hundred years after me will be under many better conditions than we are, because they will have a more complete series of photographs to refer to; but in the absence of photographs we must do the best we can. Strange though the drawing is, it brings together so many features seen in other eclipses, that there is very little doubt that it is near the truth. However that may be, it must be acknowledged that between the last drawing you saw and this

FIG. 20.—Corona of 1878.

there is a most enormous difference. The remarkable point about it is that we have no special feature in the equatorial zone: we get a streamer here with very strange outlines, and we get another there, but the point of this drawing is that we get in middle latitudes, north and south, four wonderful luminous cones, and the amount of light and structure in the corona has increased to such an extent, that that exquisite, that beautiful tracery and double curves—curves east and curves west—we saw at both poles at the minimum, are now hidden in a strong radiance. So much then for the second act, so to speak, in this solar drama.

The Maximum

We next deal with the maximum period when all the solar forces are working full time, and when we get both in prominences and in spots, and indeed in every outcome of action that we can refer to, indications of the most gigantic energies at work, and the most wonderful changes produced; energies and changes displayed from one pole of the sun to the other. When we come to this period of enormous action, we shall find that, although it becomes more general in one sense, it is really more limited in another.

The ordinary prominences, instead of clinging to the equator as they have done previously, are now found to be most frequent at the solar poles; the faculæ are brighter and more spread over the solar surface than they have ever been before. The chromosphere is richer in lines.

The spots occupy broad zones, the mean latitude being in about 18° N. and S. No spots near the poles, no spots near the equator, but spots indicating enormous activity and of enormous area, surrounded by gigantic faculæ, will be seen following each other in these zones. We shall find every one of these indicators of solar activity accompanied by enormous prominences. It is at this time we get the greatest velocities of upthrow in the prominences, and the greatest indications of tremendous downward velocity in the vapours which form the spots. It is at this time we get the spots riddled by bridges of intense brilliancy, full of veiled tints, red, yellow, blue, and violet, and all those other more delicate and beautiful phenomena described by M. Trouvelot and others, to which I have drawn attention.

How about the outer atmosphere of the sun? What has happened to that? Here, fortunately, we have the photographic records of two years—of two maximum years—to study. In these records there is no doubt that we have a thing which is absolutely and truly solar, for the reason that the photograph has undoubtedly, I think, sifted out what may be considered as due to non-solar causes. I say this distinctly, because I was fortunate enough to see both of these eclipses, one in India, and one in Egypt, and certainly there were things which I saw with the

naked eye which one does not see in the photographs. We will consider the eclipse of 1871 first.

We see in a moment that we have something here at the maximum sunspot period different from what we have had before. To compare it with the record of the preceding minima in 1867 and 1878. Instead of having streamers limited to the equator, they exist in high latitudes, and instead of having them limited to four chief maxima, as we had in the year after the minimum in 1868, the energy is now so great that they practically extend to every part of the sun.

The directions of the lines of force, as they may be called, are very various: there are straight rifts; there are curved boundaries; here another streamer is curved bodily, and so we go on. We must always remember that in this photograph what we see is, after all, a projection. We have the spherical moon in front of the spherical sun, from which these streamers project in all longitudes—some straight towards the earth, the tips of which are seen over or under the moon, some more sideways from parts of the sun nearer to or further from the eye than the central section, so that the unravelling of the appearances is very difficult, especially if the eclipse happens when either the sun's north or south pole is tipped towards us or away from us to the greatest extent.

So much for 1871: in another eleven years we have another maximum—that of 1882—an eclipse seen in Egypt. In this case we find the activity more general than in the former one. The top and the bottom of the diagram represent the north and the south poles of the sun as before; but we see now that the streamers are more broken up, and furthermore that the rifts visible round the north and south pole at the previous maximum are entirely covered up—not that the rifts were not there, but that one could not see them in consequence of the extreme brilliancy of the streamers that were thrown towards the eye from the sun between us and the plane passing through the solar poles.

Independently of that, it is easy to recognise that there is a tremendous family likeness between the photographs taken at both maxima, whereas there is the greatest possible difference between either of them and the drawings or photographs taken at the minimum sunspot period. If we accept that, that is a very great step gained.

After Maximum

We need not, after what has gone before, take up any more time, which is short, by discussing the gradual descent to minimum. I say the *gradual* descent because we know there are more years consumed in going from maximum to minimum than from minimum to maximum.

Of course all the various energies slacken down, the mean latitude of the spots and metallic prominences still getting lower till they reach lat. 8° N. and S.; then another series of spots breaks out in lat. 35° N. and S., and the whole story begins anew.

Summary

Now let us deal with the results we have arrived at. At the maximum period the continuous spectrum of the corona gives way almost entirely to a spectrum of bright lines. When I say gives way almost entirely, I mean so far as this: the striking thing when you observe the spectrum of the corona at the maximum period is a series of brilliant lines, or of brilliant circles, according as we use a slit, or simply look through a prism, and the brilliancy of the spectrum seen between these lines or rings is small compared with the brilliancy of the lines or rings. That indicates that the temperature of the gases in the corona is greater than the temperature of the other substances, and of course is very much higher than it is during the time of the minimum, when the gases do not make themselves visible, and, as I said before, the chief spectroscopic effect obtained is the continuous spectrum with dark lines here and there, showing that some part of the light is derived from cooled solid particles which can and do reflect light from the subjacent photosphere.

To deal with results, and to bring them together as sharply as may be, we find, first, that the dimness of the light and absence of bright lines at the minimum shows that the outer atmosphere of the sun is cooler at the minimum sunspot period. When I was in America in 1878, at the period of minimum to which we have referred, I saw at once that the corona was not anything like so brilliant as I had seen it previously in 1871 in India. Eventually, when the observations came to be discussed, the conclusion arrived at was that the brilliancy was not one-seventh of what it was at the previous maximum. There is a very considerable difference which no one can mistake who observes one eclipse after another.

Secondly, when the corona is thus cooler, and therefore dimmer, an extension in the plane of the sun's equator is seen. A question arises here whether this extension is not seen at the maximum because the eye is so much affected by the very brilliant corona? That is a subject which will require to be investigated in subsequent eclipses.

Thirdly, there are plenty of minor prominences at the minimum sunspot period; there are no spots, or very few.

Fourthly, the lower temperature, and therefore relative quiescence, of the solar atmosphere seems to depend on the absence of spots. That is an important matter; and the point I wish to make is this: the quietude cannot depend on the absence of prominences, because they are there—not so many of them, but still some prominences.

Fifthly, when the spots begin in these higher latitudes, 30° or 35°, as we have seen, we get the first brightening of the corona.

Sixthly, the coronal streamers follow the spots—by which I mean that the cones and coronal streamers put on their greatest intensity according as the spots have moved nearer to the equator. When we have the minimum sunspot period, you can hardly call that equatorial extension a streamer at all, because it is so very dim; and further, I take it, it is really of a different nature and origin.

The Circulation in the Sun's Atmosphere

If we make an attempt to discuss the circulation of the atmosphere, a question which we acknowledge to be an extremely difficult one, we must bear in mind the enormous difference between solar and terrestrial conditions. When a portion of the earth's surface is heated in a whole zone—as the equator is in the tropics—by the sun, you see the heat is outside, an ascending current is formed, and winds from north to south set in. For instance, if we consider the equator, and suppose the sun to be over it, we get the earth's atmosphere over that region more highly heated than those parts of the atmosphere near either pole; and the result is, we get an indraught current in that way, both from the northern and southern hemispheres. In consequence of these two currents meeting and beginning their ascent at some distance from the equator, we get a belt of calms, of reduced pressure, and we get almost perpetual rains.

Now, you see. that is all very well as a piece of terrestrial meteorology, but it is of no value to us from the solar point of view, unless it sets us thinking how very different the conditions are.

The sun cannot be heated from the outside. We have seen, in fact, that one chief point about the sun is that it is cooled on the outside; that masses of gas going up to tremendous altitudes eventually arrive where the atmosphere is cold and quiet, and where they again take on the solid or liquid forms, when they begin to go down again. Now the sun, if it is heated at all, must be heated from the inside. What do I mean by the inside? I mean—seeing that the phenomena we have been discussing in these lectures take place outside the photosphere—that the inside must be something below the level of the photosphere. Now what form must that heat take? It will take, as undoubtedly we see in the metallic prominences it does take, the form of the ejection of the tremendously brilliant and incandescent vapours. How are these produced? Something must produce them; they do not ascend of their own sweet will, or they would not come up so locally as we see them.

We get this fact most indisputably, which I hope I have been able to make quite clear, that these ascents of vapours from below the spot region always accompany the spots, and they always follow the spots in time. Then is it not reasonable to suppose they are produced by the spots? You remember I objected to the word "eruption" in connection with these prominences. I do not so much object to the word "explosion," for I cannot understand how if you get twenty million tons of meteorites falling down in a particular latitude of the sun, and plunging into the photosphere—I do not understand how there must not follow after that the most gigantic and terrific explosion, driving heated gases many hundreds and thousands of miles into the upper air along the line of least resistance, and disturbing the photosphere for months afterwards. Now that really does seem to be the plain English of what happens.

I have told you that in the origin of the spots the first disturbance is the formation of a few little openings probably by the advanced guard of the falling solid material. In a few days, by the continuous downpours, these develop into a spot. This spot is followed by a metallic prominence sending up the masses of gas at the rate, may be, of 250 miles a second—a rate Prof. Young has observed; and after that the faculæ appear. I throw that idea out because the greatest prominences are associated with the greatest spots; the spots begin the disturbance, and the energies radiate from the point where we first see the disturbance, which, I repeat, the spot begins.

We see, then, that on the sun the action will be almost just the opposite of what it is on the earth. We get first of all the descent of cooled matter on to the part of the sun where the disturbance begins.

Here we get ascent in consequence of greater heat outside. At the sun the greater heat inside the sun is liberated by the splash and explosion of spot-producing material.

Now, when the material falls in the way we have indicated, we shall get, if the idea is true, a considerable temperature in the region above the fall accompanying the return current in the shape of prominences. We may probably also get a current in the lower atmosphere set up towards the north and towards the south, and another thing we shall certainly get will be a tremendous brightening of this part of the solar atmosphere.

One of the great differences between one part of the solar atmosphere and another depends upon its temperature; so that you must imagine that the moment we get any great change in the temperature of any part of the atmosphere we must get a great change in its brilliancy, even in the higher regions: this may explain the streamers.

If there are these lower currents towards the poles there will probably be upper currents away from them which may in some way locate spot-forming material over the spot zones. On this subject, however, which, though one of the most important in solar physics, is one in which we see our way least clearly, I have not time to enter. J. NORMAN LOCKYER

(*To be continued.*)

THE INSTITUTION OF MECHANICAL ENGINEERS

THE Institution of Mechanical Engineers held their annual meeting, under the presidency of Mr. Jeremiah Head, at the Theatre of the Institution of Civil Engineers, on the 6th and 7th inst.

Mr. T. B. Lightfoot read a paper on refrigerating and ice-making machinery and appliances. He commenced by describing a complete refrigerating machine as an apparatus by which heat is abstracted, in combination either with some system for renewing the heat-absorbing agent, or, as is more usually the case, with a contrivance by which the abstracted heat is rejected and the agent is restored to a condition in which it can again be employed for cooling-purposes.

The first method by which heat is abstracted by the rapid fusion of a solid is probably the oldest. It depends upon the very strong tendency of mixtures of certain salts with water or acids, and of some salts with ice—which form liquids whose freezing-points are below the original temperatures of the mixtures—to pass into the liquid form; heat is absorbed more quickly than it can be supplied from without, and the temperature consequently falls. This method has been mainly employed for domestic and laboratory purposes.

When heat is abstracted by the second method, that is, by the evaporation of a more or less volatile liquid, other things being equal, the liquid with the highest latent heat will be the best refrigerant, because for a given abstraction of heat, the least weight of liquid will be required, and therefore the power expended in working the machine will be the least. There are four different kinds of processes employed.

The first, in which the refrigerating agent is rejected with the heat it has acquired, is generally known as the vacuum process. Water, the only agent cheap enough to be employed, must be reduced to a pressure below 0·089 lb. per square inch, which is the pressure of water-vapour at the temperature of melting ice. A vacuum-pump is employed, combined with a vessel containing strong sulphuric acid, for absorbing the vapour from the air drawn over, and so assisting the pump. Lately an improvement has been effected in this process by the employment of a pump with two cylinders and intermediate condenser, the water being admitted to the ice-forming vessels in fine streams, so as to offer a large surface for evaporation. The second, or compression-process, is used with liquids whose vapours condense under pressure at ordinary temperatures. The first apparatus employed, though in some respects crude, is yet the parent of all compression-machines used at the present time, the improvements being generally in matters of constructive detail. The water to be frozen was placed in a jacketed copper pan, the jacket being partially filled with the volatile liquid, and carefully protected on the outside with a covering of non-conducting material. A pump drew off the vapour from the jacket, and delivered it compressed into a worm, around which cooling water was circulated, the pressure being such as to cause liquefaction. The liquid collected at the bottom of the worm, and returned to the jacket through a pipe, to be again evaporated. Most modern machines comprise a refrigerator, a water-jacketed pump, a condenser, and ice-making tanks containing moulds or cells, around which brine cooled to a low temperature in the refrigerator is circulated by means of a pump. The working pressure in the refrigerator depends upon the reduction in temperature desired, the higher the pressure the greater being the work that can be got out of any given capacity of pump. The liquefying pressure in the condenser depends on the temperature of the cooling water, and on the quantity that is passed through in relation to the quantity of heat carried away; this pressure determines the mechanical work to be expended. To produce transparent ice, the water has to be agitated during freezing, so as to allow the air to escape. Various refrigerating media have been used, such as ether, sulphur dioxide, and anhydrous ammonia. The third is known as the absorption process: the principle employed is chemical or physical rather than mechanical, and depends on the fact that many vapours of low boiling-point are readily absorbed by water, but can be separated again by the application of heat to the mixed liquid. Taking advantage of the fact that two vapours, when mixed, can be separated by means of fractional condensation, an absorption machine has been brought out in which the distillate was very nearly anhydrous. Ordinary liquid ammonia of commerce was heated, and a mixed vapour of ammonia and water was driven off. By means of vessels termed the analyser and the rectifier, the bulk of the water was condensed at a comparatively high temperature and run back to the generator, while the ammonia passed into a condenser, and there assumed a liquid form. The nearly anhydrous liquid was then evaporated in the refrigerator in the ordinary way; but, instead of the vapour being drawn off by a pump, it was absorbed by cold water or weak liquor in a vessel called an absorber, which was in communication with the refrigerator, and the strong liquor thus formed was pumped back to the generator and used over again. In the fourth, which is known as the binary absorption system, liquefaction of the refrigerating agent is brought about partly by mechanical compression and partly by absorption; or else the refrigerating agent itself is a compound of two liquids, one of which liquefies at a comparatively low pressure, and then takes the other into solution by absorption. An interesting application of this system has been recently made by Raoul Pictet, who found that, by combining carbon dioxide and sulphur dioxide, he could obtain a liquid whose vapour-tensions were not only very much less that those of carbon dioxide, but were actually below those of pure sulphur dioxide at temperatures above 78° Fahr. This very remarkable and unlooked-for result may open up the way for greater economy in ice-production.

The third method is that in which machinery is used by which gas is compressed, partially cooled while under compression, and further cooled by subsequent expansion in the performance of work, the cooled gas being afterwards used for abstracting heat. This method has been much employed of late years, under the title of "Cold-air machines" for the preservation of meat and other perishable food. The author has designed machinery of this class, in which a weight of 1000 lbs. of air per hour can be reduced from 60° above to 80° below zero Fahrenheit, with cooling water at 60° F., with the expenditure of about 18 indicated horse-power. The air after being compressed in the compresser passes to the coolers, which consist of a couple of vessels containing tubes, through which water is circulated by a pump. The compressed air passes through one cooler and returns through the second, being cooled to within 5° or 6° of the initial temperature of the cooling water, which circulates in a direction opposite to that of the air. From the coolers the air passes to

the expansion cylinder, and after performing work upon the piston, and returning about 60 per cent. of the power expended in its compression, it is exhausted, having been cooled down from 70° above to 90° below zero Fahr. Besides its application to the importation of dead meat, live cattle, &c., an interesting application was made last year in the construction of a tunnel through a hill in Stockholm, in the excavation of which, some running ground was met with, consisting of gravel mixed with clay and water, which it was determined to freeze. The innermost end of the tunnel next the face was formed into a freezing-chamber by means of partition walls, which were made of a double layer of wood filled in between with charcoal. The temperature of the freezing-chamber was generally from 6° to 15° below zero Fahr. after twelve hours' running, but soon rose to freezing-point when the men began to work. The tunnel was driven through its length of 80 feet with entire success, the daily progress averaging about 1 foot.

A paper on the distribution of the wheel-load in cycles, illustrated by means of fifty-six figures, was read by Mr. J. Alfred Griffiths. The author gives the following five points of efficiency as applying to cycles generally, viz. reduction of dead weight by the avoidance of very large wheels and of heavy or purely ornamental or unnecessary framing; reduction of resistance by avoidance of very small wheels, and by employment of the best designs in bearings and in driving-mechanism for the diminution of internal friction; perfection of load distribution by entire avoidance of wheels that neither transmit motive-power nor assist the steering, and by concentration of the load on the driving-wheels and reduction of that on the steering-wheels; stability when at rest and when in motion on the straight and round curves, when on a smooth surface and also on a rough and lumpy road, and when the brake is applied either suddenly or gradually; arrangement of load and driving-mechanism so that the distribution of the wheel-load shall be as good on rising or falling gradients as on a level. Tables of dimensions and distribution of wheel-load were appended.

A paper on the raising of the wrecked steamship *Peer of the Realm*, which was effected by the platforming method, and without the aid of divers for any part of the operation, was read by Mr. T. W. Wailes, of Cardiff.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The Council of Somerville Hall have decided to build additional rooms for twenty students. Two Entrance Scholarships of 35*l*. and 40*l*. a year are offered for competition on May 25.

SCIENTIFIC SERIALS

American Journal of Science, March.—Examination of Dr. Croll's hypothesis of geological climates, by Dr. A. Woeikof. The author subjects Dr. Croll's theories to a searching criticism, traversing all his fundamental principles. The statement that the ocean must stand at a higher *mean* temperature than the land is shown to be quite erroneous, the oceans which receive cold currents from Polar seas, and even seas like the Mediterranean and Red Sea, which receive no such currents, having a mean temperature considerably lower than the continents. His whole system of estimating temperature breaks down when seriously tested, the errors being enormous, in some cases upwards of 100° F., or greater than the difference of annual temperature between the equator and the North Pole. His hypotheses, although brilliant and fascinating, cannot be accepted, the main points on which they rest being opposed to the most certain teachings of meteorology, and the whole fabric in its explanation of glaciation and geological climates generally being entirely fallacious.—Tendril movements in *Cucurbita maxima* and *C. Pepo* (concluded), by D. P. Penhallow. The author concludes generally that growth is promoted by an increase of temperature and humidity, but may be retarded by an increase of temperature when other conditions are unfavourable. It is also retarded by excessive transpiration, while the conditions favourable to growth, arising from temperature and humidity, may cause greater growth during the day in opposition to the retarding influence of light. Movements of tendrils and terminal buds, being phenomena of growth, are modified by whatever variations of condition affect growth.—Note on a method of measuring the surface-tension of liquids, by W. F. Magie. It is shown that Poisson's formula determining approximately the height of a large liquid drop standing on a level plate holds good, without any change, for a bubble of air formed in a liquid under a level plate.—Remarks on W. B. Rogers's "Geology of the Virginias" (continued), by J. L. and H. D. Campbell. In this concluding paper the authors deal with the most salient points in the higher formations of the geological system of Virginia and West Virginia. Their remarks, based mainly on personal observation, are intended to be supplementary to Mr. Rogers's comprehensive treatise on the geology of this region.—Observations on the Tertiary of Mississippi and Alabama, with descriptions of new species, by D. W. Langdon. An important result of these observations is the establishment of the relation of the Jackson beds to the Orbitoides limestone and marl beds of Byram Station. The new species, which will be figured in the forthcoming Report of the Geological Survey of Alabama are: *Verticordia eocensis*, apparently the first Verticordia described from this epoch; and *Bulla* (*Haminea*) *aldrichi*, an elongate oval shell resembling *Bulla glaphyra*, Desh.—On the area of Upper Silurian rocks near Cornwall Station, Eastern Central Orange County, New York, by Nelson H. Darton. The paper contains a careful study of the Towsend Iron Mine district and vicinity, where a small mass of Lower Helderberg limestone has been protected from the general denudation by a firm backing of coarse strongly cemented sandstones. The whole forms a ridge running just west of Cornwall Station, its more prominent geological features being shown on the accompanying map.

Rivista Scientifico-Industriale, March 15.—On the crepuscular lights that followed the Krakatão eruption, by Prof. Alessandro Sandrucci. The author surveys with Hirn the various theories propounded to explain this phenomenon, and rejects them all as inadequate, or else based on impossible assumptions. He concludes that for the present the after-glows must be classed with the numerous effects the causes of which have not yet been fathomed.—On the origin of atmospheric electricity, by Prof. Luigi Palmieri. A simple experiment is described, by which it is clearly shown that positive electricity is generated by the moisture of the air, when it becomes condensed by a lowering of the temperature. This conclusion is reconciled with the theory recently advanced by Prof. Edlund, of Stockholm, who argues that the electricity of the air is derived from the earth by the unipolar induction of terrestrial magnetism, while its return to the earth is caused by the condensation of the aqueous vapours, and especially by their conversion into the fluid state.

Rendiconti del Reale Istituto Lombardo, April 1.—Reptiles of the Orta-Kenei district, Adrianople, by Prof. F. Sordelli. This is an account of the collection recently made at the southern foot of the Balkan Range by the Cavaliere Luigi de Magistris, and by him presented to the Civic Museum of Milan. Of over twelve species of reptiles three only are found in the Po Valley, all the rest being of an essentially Eastern character, with a range extending from the Balkan Peninsula to the Iranian Plateau.—Note on a fundamental theorem in the theory of the functions of a complex variable quantity, by G. Morera.—Stratigraphic observations in the province of Avellino, by Prof. T. Taramelli. The paper contains a systematic study of the stratified rocks exposed by the cuttings of the Avellino and Santa-Venere line of railway, and ranging through the whole series from the Lower Chalk through the Eocene, Miocene, and Pliocene, to the more recent Quaternary formations.—Account of a rare and interesting ornithological specimen, by Prof. Pietro Pavesi. The author describes a fine specimen of *Bernicla leucopsis*, Bechst., recently shot at Corana in the Po Valley, and now preserved in the Civic Museum of Pavia.—On the rational curves in a linear space to any number of dimensions, by A. Brambilla.—Meteorological observations made at the Brera Observatory, Milan, during the month of March.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, May 4.—Prof. W. H. Flower, LL.D., F.R.S., President, in the chair.—Mr. E. L. Layard, F.Z.S., exhibited a fine example of a rare Beetle of the family Cerambycidæ (*Macrotoma heros*), obtained in the Fiji Islands; and a series of specimens of shells of the genus Bulimus from New Caledonia and the adjacent islands.—A letter was read from Mr. F. W. Styan, F.Z.S., relating to some Chinese ani-

mals of which he had lately obtained specimens.—Mr. W. F. Kirby read some remarks on four rare species of Sphingidæ, of which he had lately examined specimens.—Mr. F. E. Beddard read a paper containing observations on the ovarian ovum of Lepidosiren (Protopterus), and described the entrance of follicular cells into the interior of the ovum. It was believed that these cells played an important part in the formation of the yolk.—Mr. Beddard also communicated a paper by Mr. J. T. Cunningham, on the mode of attachment of the ovum of the smelt (*Osmerus eperlanus*).

PARIS

Academy of Sciences, May 3.—M. Jurien de la Gravière, President, in the chair.—On the magnetic principle, by M. Mascart. The author's theoretical studies lead to the general inference that, in a magnetic and isotropic body of any form there are three rectangular directions for which the magnetic force is parallel to the outer field with different coefficients, f, f_1, and f_2. These coefficients possess the same properties as those of a sphere of slightly magnetised anisotropic substance. For steel the mean coefficient of longitudinal magnetic force is much weaker than for soft iron; hence the increased importance of transverse magnetisation.—On the formation of oxalic acid in plants: a study of *Rumex acetosa* (sorrel), by MM. Berthelot and André. The analysis of the dried seeds of this plant yielded 0·05 per cent. of oxalic acid, which is also largely present in the leaves and stalk, but to a less degree in the root.—Remarks on MM. Berthelot and André's communication on the proportion and quantitative analysis of the ammonia present in the ground, which appeared in the last number of the *Comptes rendus*, by M Th. Schlœsing. The author takes exception to MM. Berthelot and André's account of his process for effecting the analysis, and also traverses the statement that arable land, when irrigated, tends constantly to liberate the ammonia of the ammoniacal salts contained in it.—On holmine, or M. Soret's earth X, by M. Lecoq de Boisbaudran. This was a sealed paper recently deposited with the Academy, and now opened at the author's request. It shows that holmine contains at least two metallic radicals.—On dysprosium (symbol Dy), by M. Lecoq de Boisbaudran.—Remarks on a work entitled "Science and Philosophy," presented to the Academy by the author, M. Berthelot.—Observations on the new comet 1886 *a* (Brooks I.), made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—On the spectrum of the Fabry Comet, by M. Ch. Trépied. In this comet, as in that of Encke, there appears to be a predominance of the gaseous elements on the one hand, while on the other its spectrum seems to show that the relative brightness of the nucleus bears no necessary relation to the degree of condensation of the cometary matter.—On the density of liquid atmospheric air and its constituent elements, and on the atomic volume of oxygen and nitrogen, by M. S. Wroblewski.—Practical method for the preparation of the Nicol and Foucault prisms (three illustrations), by M. L. Laurent.—On the penetration of light into deep sea-water, by MM. H. Fol and E. Sarasin. From the author's experiments it appears that layers at a depth of 300 metres are illumined every day for the whole time that the sun remains above the horizon; at 350 metres light penetrates for at least eight hours daily. Even after sunset the actinic rays seem to reach considerable depths.—On the combinations of phosphoric acid with titanic acid, zircon, and stannic acid, by MM. P. Hautefeuille and J. Margottet. The general conclusion of the author's researches is that the phosphates of titanic acid, zircon, and stannic acid possess the atomic composition of the phosphate of silica. By employing phosphoric acid as a dissolvent they can be obtained only under the octahedric form, while the phosphate of silica is obtained not only under this but under three other forms incompatible with the first.—Action of vanadic acid on the ammoniacal salts, by M. A. Ditte.—On the constitution of butter, by M. E. Duclaux.—On xenotime, a rare mineral from Minas Geraes, Brazil, by M. H. Gorceix. This substance, which on analysis yields PhO_5, 35·64, $YO + ErO$, 63·75, and insoluble residuum 0·4, appears to be a phosphate of yttria and of a second earth, very probably erbine.—On the endothelium of the inner wall of the vessels in invertebrates, by M. W. Vignal.—On the existence in birds of a series of cephalic ganglia of sympathetic character, corresponding to the segmentary cranial nerves, by M. F. Rochas.—Researches on the structure of the stomach in birds, by M. M. Cazin.—On *Entoniscus mœnadis*, a parasite infesting the *Carcinus mœnas* crab, by M. A. Giard.—On some phenomena connected with the division of the cellular nucleus in plants, by M. L. Guignard.—Remarks on M. Boutroux's recent communication on an acid fermentation of glucose, by M. Maumené. The author shows that this acid differs in no respect from that already determined and described by him in the year 1875, under the name of "hexepic."

BERLIN

Physiological Society, March 26.—Dr. Kossel communicated the results of experiments instituted by Dr. Schotten respecting the cholic acids. As was known, two different nitrogenous acids entered into the composition of the bile, glycocollic acid and taurocholic acid, which broke up respectively into glycocoll and cholalic acid, and into taurin and cholalic acid. The constitution of this azoteless acid, common to both, had not yet been determined. It was, however, known to be different with different animals. In the bile of horned cattle two cholalic acids had been found, distinguished as taurocholic acid and choleic acid. In the bile of swine a third cholalic acid had been found, hypocholalic acid; and in the bile of geese, a fourth, chenocholalic acid. It was probable that still more cholalic acids would be discovered. Dr. Schotten's studies had for their object the elucidation of the constitution of cholalic acid. By heating to 300° C. he was able to split two molecules of water, and to obtain a body of an equal quantity of carbon, a less quantity of hydrogen and of oxygen. By subjection to a still greater degree of heat, from two molecules of the acid a molecule of water was separated, and a substance obtained consisting of two groups of atoms connected by an atom of oxygen. By treatment with anhydrous acetic acid Dr. Schotten established that cholalic acid was both monobasic and monovalent. Finally he investigated the composition of human bile from 350 gall-bladders, with a view to testing the statement that in human bile was contained a peculiar cholalic acid, the anthropocholalic acid of Herr Beyer. Although at first he received the same results, viz. a salt of baryta containing much less carbon than the other cholalic acids, yet subsequently, by continued purification and transcrystallisation of the product, he came to the conviction that in the human bile only the taurocholic acid of horned cattle was present. The results at first obtained of apparently different significance were due to the fact that the soluble barytic cholalate with carbonate of barium very readily formed insoluble double salts which were not easily split.—Dr. Biondi spoke on the intermaxillary bone, and discussed the fact that the doctrine set up by Goethe, that on each side but one intermaxillary bone was developed, namely from the frontal process, while the superior maxilla, on the other hand, was evolved from the maxillary process of the skull, had, in the year 1879, been replaced by a new doctrine advanced by Herr Albrecht. According to this new doctrine two intermaxillary bones were developed on both sides, growing out of the lateral and median frontal process, and then coalescing with the superior maxilla from the maxillary process. According to the older view, at present defended in particular by Dr. Kolliker, the hare-lip originated between superior maxilla and intermaxillary bone. Prof. Albrecht, on the other hand, removed the position of the hare-lip to between median and lateral intermaxillary bone. By way of proof for this latter view, the circumstance was adduced that externally from the fissure an incisor tooth was regularly found. Dr. Biondi had examined a very large number of normal and pathological skulls, and had followed the development in embryos of the facial bones. Like Prof. Albrecht, he regularly found an incisor tooth externally from the hare-lip fissure, and, in the case of embryos, in the intermaxillary bone two points of ossification, whence were developed two separate intermaxillary bones. Between these two were situated the hare-lip fissure and that of the palate. The views of Dr. Biondi and of Prof. Albrecht deviated on the contrary very materially from each other respecting the place where the two intermaxillary bones originated. In accordance with the speaker's views, the superior maxilla and the outer intermaxillary bone developed from the maxillary process, while, on the other hand, the inner intermaxillary bone sprang from the median frontal process. The lateral frontal process did not reach so far down. The hare-lip, in point of fact, therefore, as had been maintained by earlier authorities, was situated between the maxillary and frontal process. The upper lip, in the opinion of the speaker, developed itself, in perfect accordance with the relations obtaining in respect of the superior maxilla and its alveolar margin, out of the maxillary process and the inner frontal process, while the

outer frontal process formed the alæ nasi. In respect of the two intermaxillary bones on each side, the presence of which the speaker assumed along with Prof. Albrecht, Dr Biondi deviated from the latter in so far as that he had found, not an outer and inner intermaxillary bone on each side, but an anterior and posterior. The incisor teeth, as also the supernumerary teeth, developed themselves only in the intermaxillary bone. Dr. Biondi illustrated his address by preparations, drawings, and photographs he produced.—Dr. Pohl-Pincus next gave a supplement to his address on the polarisation colours of the hair of the human head, adducing the reasons which determined him to lay down three types of colouring: the normal, the pathologic, and an intermediate type. It was nevertheless to be understood that a whole series of transitionary hues intervened between the two extremes. He further stated that, in accordance with his experience, hair pathologically changed in its double refraction in consequence of stimulation from inflammation or from psychical excitement was long in returning to its normal condition. The speaker next described two experiments on a frog's heart. When he removed from a frog the anterior part of the cerebrum, under avoidance of heavy bleedings, then set free the heart, and stimulated one or several sensory nerves of the body, he then observed that the systole of the heart was unchanged. During the diastole, however, there appeared on the surface a chess-board-like drawing, and the diastole itself was interrupted in the middle by an intermission. By stimulation of the vagus he was able to overcome this effect of the irritated sensory nerves. The second observation he communicated respected the local diastole which a considerable time previously had been noticed by others as well as by himself. The occurrence of this diastole under local mechanical stimulation of the frog's heart was always a very uncertain one. Dr. Pohl-Pincus had now quite recently found that the local dilatation took place only when the stimulation was given during the second half of the systole. At the beginning of the systole, on the other hand, the stimulation had no effect whatever, and during the diastole it even gave rise to local systole. The effects of the local mechanical stimulation lasted some time, and, besides the local contraction or relaxation, manifested itself in a heightening of the diastolic or systolic state on each occasion at the stimulated spot.

Physical Society, April 2.—Prof. du Bois Reymond spoke on the irreciprocal conduction of electricity found by him in the electrical organ of fishes, and discussed the teleological significance of this property for the capability of fishes to discharge strong electrical currents outwardly (NATURE, vol. xxxiii. p. 407).—Following up the address at the last sitting by Dr. Baur, Dr. Pernet spoke on some other more recent thermostats, in particular on those which effected the regulation by means of vapour pressure. In the closed short leg of a manometer was a small quantity of a fluid readily susceptible of evaporation; above it was placed quicksilver, which also filled the long leg of the manometer. The short leg of the manometer with the fluid referred to lay in the bath, the temperature of which should be kept constant. Did the temperature rise above the desired degree, then the quicksilver of the manometer also mounted in consequence of the pressure of the vapour, and the flow of the gas to the flame got thereby in part shut off. The temperature than sank, the vapour condensed, and the quicksilver in the manometer fell. To render the apparatus available at every over-pressure, the manometer was cut through and connected by a movable piece of tube. As the material best adapted for these flexible connections, the speaker recommended thin steel tube, which was coated over with lead, thereby rendering it easily pliable and not liable to any elastic after-effect. The regulation by means of the long manometer tube was accomplished in an electrical way by an electro-magnet. The details of the arrangement of the thermostats in question were illustrated in part by models, in part by drawings. As fluid for very low temperatures, a mixture of two hydrochloric ethers was used; for higher temperatures, a mixture of ether and alcohol; for temperatures above 100° C., water; and for still higher degrees of temperature, other fluids. With respect to the efficacy of these thermostats, the speaker adduced that he was able to keep a water-bath for a considerable length of time constant to within 0°·02 C.—Dr. König laid before the Society a photometer sent to him from Messrs. Yeates and Son, of Dublin, which apparently far surpassed the Bunsen photometer. It consisted of two quadratic prisms of cast paraffin connected with each other on a longitudinal side. Between these two prisms was placed a silver leaf or a tinfoil leaf. When light from one source fell on the one prism, then it appeared clear white on account of the diffused reflexions. The light was able to penetrate to the other only through the metal sheet. The other prism therefore appeared dark. If a second light was placed on the other side, then the other prism appeared likewise bright. By displacement on a scale the photometer could be brought into the position in which both sides appeared equally bright. The distance from each other of the two sources of light gave in that case the relation to each other of the intensities. The speaker proposed some arrangements which would render this photometer available for coloured light as well. Similar proposals for this purpose had already been made by Dr. Jolly.—Dr. König further made some supplementary communications on the case recently discussed by him of anomalous colour-seeing arising from alcoholism. After determining that the occurrence of a neutral point in the spectrum was a perfectly certain proof that the eyes in question perceived only two fundamental colours, he investigated the extension of the colour curves by the employing of mixed colours, and thereby obtained important results, which he promised to communicate to the Society in a complete form in May or June next.

BOOKS AND PAMPHLETS RECEIVED

"Hand-book of Plant Dissection," by Arthur, Barnes and Coulter (Holt, New York).—"Manual of Physical Geography of Australia," by H. B. de la Poer Wall (Robertson, Melbourne).—"Journal of the Chemical Society," May (Van Voorst).—"Papers and Proceedings of the Royal Society of Tasmania for 1885" (Tasmania).—"Journal of the Royal Agricultural Society of England," April (Murray).—"Proceedings of the Bath Natural History and Antiquarian Field Club," No. 1, vol. vi. (Davies, Bath).—"The Topographic Features of Lake Shores," by G. K. Gilbert (Washington).—"Oils and Varnishes," by J. Cameron (Churchill)—"Year-Book of Scientific and Learned Societies, 1886" (Griffin).—"Notes on Analytical Chemistry," 2nd edition (Churchill).—"Mountain Ascents," by J. Barrow (Low).—"Dogs in Disease," 2nd edition, by Ashmont (Low).—"Bulletin de la Société Impériale des Naturalistes de Moscou," Nos. 1 and 2 (Moscou).—"British Petrography," part 4, by J. J. H. Teall (Watson, Birmingham).—"Missionary Work among the Ojibway Indians," by Rev. E. F. Wilson (S.P.C.K.).—"Our Island Continent," by Dr. J. E. Taylor (S.P.C.K.).—"A Manual of the Diseases of the Elephant," by J. H. Steel (Moore Madras).—"A Treatise on Elementary Statics," by J. Greaves (Macmillan).

THE YEAR-BOOK OF PHARMACY

Year-Book of Pharmacy, 1884. (London: J. and A. Churchill, 1884.)

THIS volume contains the transactions of the British Pharmaceutical Conference at Hastings in August 1884, in addition to abstracts of papers relating to pharmacy, materia medica, and chemistry, from July 1, 1883, to June 30, 1884. The work is of course especially intended for chemists and druggists, but it also contains some information to general readers, and as this might be apt to be overlooked from the special nature of the work, we shall extract from it somewhat more largely than we might otherwise do. Amongst the most striking facts it contains is an observation of Sachs regarding the effect of light on plants, mentioned by Mr. Williams, President of the Conference, in his address. This observation is not only interesting in itself but it appears to give a reason for the rules which the herbalists, centuries ago, laid down for the collection of medicinal plants, and which in modern times have been regarded as simple nonsense, and have consequently been abandoned. The herbalists were particular about collecting their herbs at certain hours of the day or night, and even at special phases of the moon. We have not yet got any exact information regarding the effect of the moon upon the chemical composition of plants, but Sachs's observations show that the amount of starch present in the leaf of any given plant varies considerably under different circumstances. In direct sunshine and under otherwise favourable circumstances, starch is formed very rapidly; but it generally disappears entirely during the night, so that a leaf collected in the evening will prove full of starch, while another leaf of the same plant collected before sunrise will not show a trace. But even in direct sunshine, with all the necessary warmth and moisture, the plant will not form starch if the air in which it is growing be deprived of carbonic acid by means of caustic soda. The method of ascertaining the presence of starch in a leaf is very simple. "The leaf to be examined is first plunged into boiling water for about ten minutes, then taken out and digested in alcohol for about the same time (methylated spirit answers perfectly well). This treatment extracts the whole of the colouring-matter (chlorophyll), and leaves the leaf perfectly white. The leaf is now placed in an alcoholic solution of iodine, and the presence or absence of starch is demonstrated in a few minutes. The absorption of iodine commences at the edges, and soon colours the leaf blue-black if much starch be present, or brown if the quantity of starch be but small. The venation of the leaf appears as a pale network on a dark ground, rendering it a very beautiful object, but all my efforts to preserve a specimen beyond a few hours have hitherto failed." The variations in the amount of starch in the leaves at different periods of the twenty-four hours are peculiarly interesting as rendering it probable that the amount of alkaloidal or other active principles may also vary in a similar way. Since the publication of this book other researches have been made which render such a variation all the more probable inasmuch as they show that some of the poisonous alkaloids formed by the putrefaction of albuminous substances are identical with those occurring in some plants.

In the chemical section of this Year-Book there are several articles on putrefaction-alkaloids or ptomaines. These alkaloids were shortly after their discovery supposed to differ in certain respects from the alkaloids produced by plants, but the points of difference on which reliance was at first placed in order to distinguish between alkaloids which might be formed in a dead body and poisons of vegetable origin which might have been administered for the purpose of producing death have now been shown to be untrustworthy for this purpose. Amongst the most important of the researches on this subject are those of Brieger, some of which are abstracted in this Year-Book, and others of which have been since published in his works ("Ueber Ptomaine" and "Weitere Untersuchungen über Ptomaine," Berlin, Hirschwald). The abstract of another paper by Poehl in this Year-Book contains interesting information regarding alkaloids formed by the decomposition of rye-meal. His results are that ergot and mould have a peptonising action on the albuminous matters of the meal. The degree of putrefaction of albumens is directly proportional to their peptonisation. In the first stages of putrefaction the decomposition of albumens is greater in ergot meal than in mouldy or pure meal. But in the more advanced stages these differences are not so marked. Various alkaloidal products were obtained both from pure and tainted meal after they had been allowed to putrefy. This fact may be of considerable importance in regard to the action of alcoholic drinks. Guareschi and Mosso in a paper abstracted in this Year-Book describe the methods by which they obtained from putrefying fibrine an alkaloid having an action similar to curare. In another work, which is not abstracted here ("Les Ptomaïnes," Première Partie, Rome, Turin, Florence, H. Loescher), they mention that one of the difficulties they had to contend with was the presence of organic alkaloids in different kinds of alcohol. If we consider that a great deal of the spirits used for ordinary consumption are made of so-called silent spirit flavoured with various substances, and that silent spirit is also used in fortifying wines, it is evident that the purity of this spirit is of very considerable importance; but we believe that silent spirit is sometimes obtained by the fermentation of grain which has become mouldy or decomposed to such an extent as to be useless for food, and volatile alkaloids formed during its decomposition will pass over in the process of distillation, and being thus present in the spirit so produced may injuriously modify its action.

The most interesting of the other facts contained in this Year-Book are those which refer to the synthesis of organic alkaloids. Hofmann has shown that piperine, the alkaloid of pepper, can be built up from pyridine, a coal-tar base, and that piperidine, one of the intermediate compounds, which is also obtained with piperic acid when natural piperine is split up by potash, is probably a stepping-stone to the formation of conine and atropine. It was mentioned in a former Year-Book that caffeine, the alkaloid of tea and coffee, can be prepared from theobromine, the alkaloid of cocoa, which in its turn can be obtained from xanthine, a substance which is present in

beef-tea or Liebig's extract, and lastly, xanthine can be obtained from guanine, so that it seems not improbable that the manufacture of caffeine for medicinal purposes from Peruvian guano may be looked for as a consequence of the researches already made on the chemistry of these substances.

EUCLID REVISED

Euclid Revised, containing the Essentials of the Elements of Plane Geometry as given by Euclid in his First Six Books, with numerous Additional Propositions and Exercises. Edited by R. C. J. Nixon, M.A., formerly Scholar of St. Peter's College, Cambridge. (Oxford: Clarendon Press, 1886.)

THE movement for greater freedom in the teaching of elementary geometry than is consistent with a rigid adherence to Euclid's Elements, which may be regarded as having taken definite shape with the formation of the Association for the Improvement of Geometrical Teaching in the year 1871, gains strength surely, if not rapidly. Of this Mr. Nixon's book is one of many indications, notwithstanding his decision in favour of retaining Euclid's Elements as the basis of geometry. For this decision he assigns "*two* substantial reasons of expediency and convenience:—

"(1) That an established *order* of geometric proof is convenient for examination purposes;

"(2) A recognised *numbering* of fundamental results is convenient for reference."

He adds, "as co-operative reasons—the fact that there is no consensus of opinion among experts as to the superiority of any other scheme yet proposed; and the sentiment of repugnance at the thought of sweeping away an institution rendered venerable by the usage of more than 2000 years."

It may be questioned whether Mr. Nixon's first reason "of expediency and convenience" leads as a consequence to the retention of Euclid as a class-book. The experience of the examinations of the University of London is held by many examiners as well as teachers to prove the contrary. But apart from this we would enter our protest against the subordination here, as so often elsewhere, assumed of teaching to examination, of teachers to examiners. Examiners are doubtless strong, but teachers, if they will only combine and assert their convictions in practice, are stronger. We believe too that those who have most carefully considered the question of a rival order of sequence of geometrical propositions would agree that the best order in a logical arrangement does not seriously *conflict* with Euclid's order, except by simplifying it. Rather, by bringing the proofs of each proposition nearer to the fundamental axioms and definitions than Euclid does, it renders less assumption of previous propositions necessary for the proof of any given proposition. It stretches the chain of argument straight instead of carrying it round one or many unnecessary pegs.

Many instances of this may be found in Mr. Nixon's own book. To mention one only—the proof which he judiciously gives of the fundamental proposition that "similar triangles are to one another in the duplicate ratio of their homologous sides" depends directly on the 1st Proposition only of the Sixth Book, instead of the chain being carried round the unnecessary peg of the 15th Proposition, as it is by Euclid himself.

Waiving, however, farther discussion of these general considerations, and granting Mr. Nixon his postulates of expediency and sentiment without farther cavil, we have no hesitation in thanking him for having produced a good and useful book. The conditions under which he has worked are such as to make it unsatisfactory to one who seeks for a natural and symmetrical sequence and grouping of propositions forming a well compacted whole, but all the materials are there for enabling the student, if he has sufficient patience, to make it for himself. The book is well furnished with important propositions not contained in the ordinary editions of Euclid, but various excrescences in the shape of addenda and lemmas have been necessary to accommodate them, and in these addenda those which are of real importance for after use are rather hidden amid a crowd of other consequences, interesting as results, but not necessary parts of the geometrical edifice.

Mr. Nixon has, wisely as we think, distributed his axioms and definitions among the propositions, introducing each one exactly when it is required, instead of commencing with the full series, but it seems to us a serious defect that they are neither numbered nor anywhere collected together for reference. We are rather surprised that he has not taken the opportunity of revising Euclid's editors, and reverting to Euclid's division, into common notions and postulates, of what modern editions call the axioms and postulates; the common notions embracing those general axioms which are true for all magnitudes, while the postulates relate to geometrical magnitudes only and are the really essential basis of geometry.

While retaining the order of Euclid's propositions, Mr. Nixon has very freely revised his demonstrations both in substance and in form. Where he has introduced new demonstrations, they are in all cases, we believe, improvements. The famous *pons* disappears in favour of a proof founded on turning the triangle about one of its equal sides till it falls again into its original plane. Philo's proof of i. 8 is adopted, and consequently i. 7 omitted as useless. In Book II. the diagonals of the rectangles disappear. Euclid's propositions about the correspondence of equal chords, arcs, and angles at the centre of a circle are proved directly by superposition, as recommended in the Syllabus of the Geometrical Association, to which here as elsewhere Mr. Nixon acknowledges his indebtedness, but he still retains the propositions about similar segments which we should have expected him to omit (as in the case of i. 7), as thereby rendered useless. Book V. contains the essentials of the theory of proportion, deduced from Euclid's definition, in the form first suggested by De Morgan. In Book VI. superposition is often employed, where Euclid makes a separate construction, but not invariably, as, we think, might have been done with advantage.

We are less satisfied with the form of Mr. Nixon's demonstrations than with their substance. He objects strongly to Euclid's "prolixity," of which he goes so far as to say, after twenty years' experience as a teacher, that "NOTHING is so great a hindrance to the learner." We doubt this, speaking also not without experience. In

some respects Euclid's prolixity, recalling over and over again propositions which have gone before, does much to fix them in the memory of the learner and prevent looseness in reasoning, and though we think Euclid's style admits with advantage of some pruning, we feel that Mr. Nixon, with overstrained regard to the examination hall, has used the knife too freely, and has run the risk by his style and free use of abbreviations and signs of letting the young pupil believe, as he is only too glad and ready to do, that mathematical work should be written after the fashion of a telegram, grammar disregarded, articles and little words omitted, and what should be sentences written without verb or copula.

Mr. Nixon has deliberately omitted the usual marginal references, on the ground that "learners (1) very generally ignore them; and (2) will gain greater benefit by having to hunt up the references themselves." We believe he has thereby seriously injured the value of his book. Because many boys, in the hands of a careless teacher and left to themselves, ignore the references, is hardly a good reason why they should not be supplied for those who would use them, or who would be required by their teacher to use them; and they would be exceptional pupils under exceptional teachers who could be depended on, or find it easy, "to hunt up the references themselves." Doubtless the exercise of doing this is excellent, but the beginner needs some help in doing it.

We have thought it would be most useful to dwell at some length on Mr. Nixon's revision of Euclid's text, and can only notice generally the exercises and addenda, which occupy more than half the book. The collection of exercises appears to be very well chosen and complete, though we should have been glad to see more of them interspersed among the propositions from which they naturally flow.

The addenda include all the more important developments of the elementary geometry, as well as an introduction to many of the methods of the higher geometry. As a collection of results in the geometry of the straight line and circle this part of the book appears to us from a cursory perusal to be excellent, giving a full account of the important relations of the triangle and its associated circles, centres of similitude, coaxial circles, &c.; while for methods the elementary notions and use of cross ratios, harmonic ranges, inversion, poles and polars are explained and applied to such an extent as to prepare the student naturally for their application to geometry beyond that of the straight line and circle. We fail, however, to find such prominence given to the great principles of duality and reciprocity as their importance, scarcely less in elementary than in the higher geometry, appears to us to demand.

The typography, and the accuracy and clearness of the figures, are to be commended as worthy of the Clarendon Press.

R. B. H.

OUR BOOK SHELF

Practical Histology and Pathology. By Heneage Gibbes, M.D. Third Edition. (London: H. K. Lewis, 1885.)

THE text in this edition does not, on the whole, differ much from that of the previous editions, some new useful formulæ of staining and a more comprehensive arrangement of the subject-matter being the chief differences.

The tables given at the end of the book as to the conversion of degrees of Centigrade into Fahrenheit and *vice versâ*, as to the conversion of English weights and measures into French, are in some points incorrect, and might have been easily correctly copied from any standard work.

E. KLEIN

Farm Live-Stock of Great Britain. By Robert Wallace, F.C.S. F.H.A.S., &c., Professor of Agriculture and Rural Economy in the University of Edinburgh. (London: Simpkin, Marshall, and Co.; Edinburgh: Oliver and Boyd, 1885.)

WITHIN 200 pages octavo, of rather large type, does Prof. Wallace condense much useful information upon farm live-stock. It must, however, be evident that to treat of cattle, sheep, swine, and horses, from a biological, an agricultural, and an economical point of view would at least require double the number of pages, containing twice the number of words, and folded quarto. Brevity has been said to be the soul of wit; but in a work such as this we cannot but feel that it must be intended by its author either for those who know nothing or for those who know something of the subject. It appears to us to fall short of the requirements of each of these classes of readers. Four and a half lines—forty words, in fact—upon the Devon breed of cattle cannot be considered adequate, however terse and compressed they may be (and to the point they undoubtedly are), to giving a good word-picture of this race. Besides, Prof. Wallace must excuse us for differing from him as to his statements even in this very short description. He is wrong in saying "colour blood-red, no white." There is white upon the fore-udder in almost all Devon cattle, and it is unfortunate that there should be a manifest error in this very short description of an important breed.

The book aims at too much, and is too vague in its general plan. The writer is successful in being concise, but he is not free from errors, and a greater amplitude in his observations would have both conferred a greater general interest upon his pages, and been more satisfactory to an earnest student of agriculture. Let us hope shortly to see an enlarged edition.

Common-Sense Euclid. Books I. and II. Part I. By the Rev. A. D. Capel, M.A., St. John's College, Cambridge. (London: Joseph Hughes, 1886.)

THE object of this book, as the author tell us, is to point out, especially to teachers and those teaching themselves, the portions of the treatise which either present difficulties to the beginner or escape their notice altogether.

The propositions are explained in a very clear and concise way, some of them being even worked backwards and their analysis being made in every case; explanations are given, here and there, where they are most required, and are put in the easiest possible way. Problems, at the end of each proposition and also at the end of the book, are given, making a total of 300, followed by hints for their solution.

The figures are not placed opposite each proposition, as they are in most editions, but all together at the end. The plan adopted is a very good one, it being understood that the student must construct the figures for himself.

J.

Arithmetic for Schools. By the Rev. J. B. Lock, M.A. (London: Macmillan and Co., 1886.)

THIS is a carefully prepared school-book, forming, as to scope, a sort of arithmetic mean between Hamblin Smith's and Brook Smith's or Muir's. It contains the usual rivulets of text ending in seas of examples. In the purely arithmetical part of the book logical accuracy is attempted with considerable success. Want of grasp is much more evident in the part which deals with the applications. There the division into subjects is strangely illogical, and

slight inaccuracies of thought and language occur. Is it really the case, for example, that rate of interest (p. 181) is totally independent of *time?*

LETTERS TO THE EDITOR

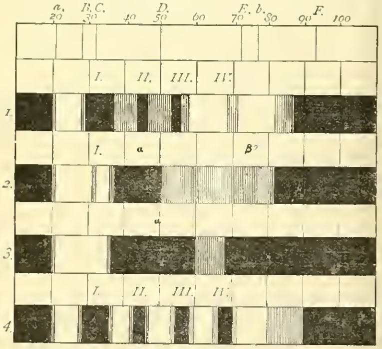
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Chlorophyll

IN a short note in NATURE (vol. xxxii. p. 342) I mentioned the discovery of a colourless substance produced by the action of reducing agents on chlorophyll and regenerating, on being exposed to the air, the original green solution. I may be allowed to add to my previous statement that if this reaction is not pushed too far and the resulting substance is duly concentrated, it is not colourless, but of a reddish-brown by daylight, of a splendid ruby red (very different from the well-known port-wine red colour of chlorophyll) by limelight. Its spectrum is chiefly characterised by the total absence of band I., and the presence of a broad band corresponding exactly to band II., and the two intervals between I. and II., and between II. and III. Band IV. seems also to be present, though somewhat altered in its position and intensity.

The presence of a slightest trace of oxygen is immediately announced by the appearance of the I. chlorophyll band, so



that the reaction may be considered as a most sensitive test for oxygen. On further exposure to the air, as already mentioned, chlorophyll is regenerated. This new substance being evidently a product of reduction of *chlorophylline*, the green-colouring matter of chlorophyll isolated and described by me in 1869, it may be called *protochlorophylline*, or simply *protophylline*.

Its solutions can be kept in sealed glass tubes containing H_2 or CO_2: *in this latter case in a dark place, for on being exposed to light they turn green.* Can it be inferred from these facts that the oxidation takes place at the expense of CO_2—that carbonic acid is actually reduced under the joint action of light and of a chlorophyll solution? The question, if answered in the affirmative, is of so great importance, that I am now taking all the pains to arrive at a definite conclusion.

The optical properties of *protophylline* seem to indicate its presence in freshly-prepared chlorophyll solutions. Indeed the difference presented by the spectrum of a freshly-prepared green solution and that of Mr. Stokes's *modified chlorophyll* may be easily accounted for by the presence in the former of the broad *protophylline* band intercepting the rays of light in the two intervals between the bands I. II. and III., as just mentioned. To the presence of different quantities of *protophylline* may be likewise attributed the varying relative intensity of the bands II. III. IV.,—a fact that has attracted the attention of many observers.

At all events, it cannot be doubted that the study of this curious substance, though attended with considerable difficulties, all the operations taking place in a total absence of oxygen, and under the continual control of the spectroscope, will throw a new light on that most important of physiological problems—the part played by chlorophyll in the decomposition of carbonic acid by the living plant. The Stone Age in the Malay Peninsula

IN NATURE, vol. xxxiii. p. 377, there is a notice of a paper by M. de Morgan, published in *Cosmos*, on the Stone Age in the Malay Peninsula. Will you permit me to offer a few remarks with reference to this matter. In the first place, it is said that M. de Morgan came into contact with three native races, which he respectively names Sakayes [Sakai], Seumangs [Sĕmang], and Rayats [Ryot]. I have put in brackets the commonly-accepted spelling in the Straits. It is funny what peculiar mistakes travellers make when passing through a country the language of which they do not understand, ryot being the word used in the Straits to express those followers or retainers of a native chief who are not actually his debt slaves, but who owe him more or less of feudal allegiance; Malays here invariably use the word when speaking of the following of a Sakai chief. The word ryot is, I believe, also used in the same sense in India. With reference to the tribes of whom M. de Morgan speaks as living in the recesses of the mountains, and whom the Sakaies called "fire apes," I cannot help remarking that I have never heard the Sakaies speak of them myself, nor can I find that any other Government servant here has heard of them either; still we are in pretty constant communication with certain of the Sakaies of these hills, and for my part I have at different times stayed for longer and shorter periods at the clearings of some of the chiefs whom M. de Morgan visited, and moreover I have employed most of the same Malays who followed M. de Morgan. By the bye, these were Sumatran Malays, and they told me some very extraordinary tales about the wild tribes before I started up country with them; these foreign Malays are especially addicted to telling marvellous tales of the wild tribes of the mountains, but so far I have not been able to verify their information in the least degree either from the Sakaies themselves or from native Malay sources. It would be interesting to know what equivalent was used for the expression "fire apes." Was it a Malay word or a Sakai word? With reference to the Stone Age I quite agree with M. de Morgan in believing that at a not very late period—probably just before the Malay invasion—there were tribes living in the interior who were not acquainted with the use of iron; up to the present moment I have been able to collect twenty-two stone implements. I have sent drawings and notices of these to the Anthropological Institute. I may, however, here mention that of these twenty-two specimens one is the half of a stone bracelet; the rest are all chopping-tools of different descriptions, used, I think we may fairly conclude, by a race of boat-builders, who most likely constructed dug-outs, much like the Malays of the present day. I adduce this supposition from the fact that of my twenty-one specimens two are perfect gouges, and six others are of the description which Dr. Evans has classed under adzes. The cutting-edges of nearly all my specimens have been considerably damaged by use. The high polish which M. de Morgan's specimens—and mine also—exhibit is, I think, accounted for in a great measure by the fact that they are used and very highly prized by the Malays as whetstones; the women preserve them, especially to sharpen their razors on, with which they shave the heads of their children during the periods ordered by custom or religious law; and the men were, until lately, very anxious to procure them to sharpen the iron spurs used in cock-fighting. As almost all of the specimens procured by me have been purchased of Malays who have inherited them from their ancestors, and prized them as heir-looms, it is, I think, reasonable to suppose that in their original condition some of them, at least, were considerably rougher than when they came into our hands; this supposition is further confirmed by a remark made to me the other day by a Malay chief. He said that he once had a thunderstone given to him which was so rough that he had to wear it down on his emery-wheel before he could use it as a whetstone. I have one specimen which has no cutting-edge, but is squared off at each end and is almost spindle-shaped. I have

also seen another specimen of the same description. [illegible] that these two specimens have been manufactured by Malays for whetstones out of the so-called thunder-stones? I cannot account for them in any other way; they are too slight for hammers.

For my part, I have always found the Sakaies especially wanting in every respect as to traditions beyond the memory of their own generation, and they have invariably answered my inquiries as to the origin of the stone axes by saying, like the Malays, that they are thunder-stones. To such an extent is this belief held by Malays, that the other day a Malay of considerable social standing assured me that once a cocoa-nut palm was struck by lightning close to his house, and that about a month afterwards he searched about the roots of the tree and found the thunder-stone which was the cause of the damage: it was this man's father who for several years kept a fire alight in his house, which fire was generated from the same tree after it had been struck by the electric current.

I have already drawn attention to the Malay belief as to these so-called thunder-stones (NATURE, vol. xxxii. p. 626). My specimens are all in the Perak Museum at Thaiping.

On a Thermo-electrical Phenomenon in Connection with Prof. Balfour Stewart's Paper on Terrestrial Magnetism

IN the *Philosophical Magazine* for May Prof. Balfour Stewart, in his paper "On the Causes of the Solar-Diurnal Variation of Terrestrial Magnetism," takes in one place (p. 443), for an example, the case of "an ordinary electric circuit, say of a circular shape, and horizontal, and heat it by causing some source of heat, such as a lamp, to travel slowly around it with a definite rate of progress." He goes on to say that no current due to the heating will take place. So it would generally be thought. If, however, the experiment be even roughly tried, at all events with an iron or nickel wire, the contrary takes place. An account of the experiments, &c., which I have made on this subject, was read before the Royal Dublin Society on March 24, and will, in the course of time, be printed in the Society's *Proceedings*. Though there is a current in a wire on causing a heated portion to travel along it, it seems unlikely from the nature of the phenomenon that it could in any way be inferred that the higher air would similarly affect a current under the sun's heating. Do Migratory Birds Return to their Old Haunts?

MUCH evidence has been given by naturalists to prove that birds of passage return to their old haunts. The following, I think, may be of interest to some of the readers of your valuable paper. For the past two springs a cuckoo gifted with a decidedly peculiar note has visited this neighbourhood. Within the last fortnight it has again arrived. Its song consists of three clear distinct notes, cuck—coo—coo, the second note being a semitone above the last. This it never varies. We all know that towards the end of its sojourn the cuckoo suffers from hoarseness, or, as the country people say, "changes its tune." Although this bird suffers in a similar way, yet it still maintains its peculiar song—three notes. As far as I can ascertain, it does not wander beyond the same limits—from the park here to a little hill about half a mile distant. I think these facts not only conclusively prove that the cuckoo returns to its old quarters year after year, but that it also restricts itself during its stay in this country to the same locality. F. C. TAYLOR

Summerleaze, East Harptree, May 13

The Poison of the Stinging-Nettle

IN the interesting article in your issue for May 6 (p. 5), on "Plants and their Defences," there is one sentence on which I should like to be allowed to offer a few remarks. It runs thus:—"This fluid [of the stinging-gland of the stinging-nettle] is generally conjectured to be formic acid—a view based on the fact that this acid can be obtained from the nettle-plant by suitable means." Does this "conjecture" rest on any other basis than the similarity of the effect produced by the sting of the nettle and the bite of the ant? I am inclined to think not. Certainly the fact that formic acid can be obtained from the nettle-plant is not in itself a cogent argument, seeing that it has [illegible] cell-sap of living plants is a widely-spread constituent of the [illegible] harmony with the fact that the fluid contained in the [illegible] glands of the nettle has frequently, if not always, an alkaline reaction. It seems strange that we have at present no trustworthy observations on so interesting a question. Can none of our physiological chemists come forward and remove it from the region of conjecture? ALFRED W. BENNETT

St. Thomas's Hospital, May 13

What is Histioderma?

CAN any of the readers of NATURE inform me to what class of fossil organisms belongs the genus Histioderma? Mention of the name—but of the name only—is made by Sterry Hunt in this journal, vol. vi. (1872), p. 54, and by Hicks in the *Quarterly Journal* of the Geological Society of London, vol. xxix. part 1, 1873, table facing p. 42. It does not occur in Broun's "Index Palæontologica," in Pfeiffer's "Nomenclator Botanicus," nor in Scudder's "Zoological Nomenclator." The name is not to be confounded with that of Carter's genus, Histoderma, established 1874, for recent sponges. S.

Leyden, May 15

ON THE INFLUENCE OF FORESTS ON THE CLIMATE OF SWEDEN[1]

A VALUABLE Report on this subject has been prepared by Dr. H. E. Hamberg, and printed as an appendix to the Report of the Forest Commissioners of Sweden for the year 1885. The observations were commenced in 1876, on the principles established by Dr. Ebermayer in Bavaria, but Dr. Hamberg soon found that the mere comparison of the results obtained at the forest station with those yielded by its sister station in the open country was insufficient to bring out all the peculiarities of forest influence, and accordingly he added a third class of station, situated in a clearing in the forest itself (*öppen plats i skogen*). The various results of these observations are discussed in a very exhaustive manner, and we must refer those interested in the subject to the Report itself. The author's conclusions, however, are very interesting, and are reproduced here in full.

"Our researches do not allow us to determine whether the presence of the forests on the whole contributes to increase or diminish the quantity of heat in the atmosphere, that is to say, to raise or lower its temperature. In fact, we have been entirely unable to take into account either solar radiation or the radiation from the needles[2] and the points of the trees. Until we are able to ascertain the quantity of heat which escapes from these surfaces, and its relation to that escaping from other surfaces, it is quite impossible to determine with certainty the influence of the forest on such an important subject as the mean temperature, and must confine ourselves to approximate estimations. Among the various surfaces which are met with in Sweden the most important are assuredly water, bare ground or rock, soil covered by herbage, and finally forest. Neither the surface of the lakes and sea nor the bare soil of town streets have any resemblance to the forest: the climate of the latter bears no similarity to a maritime climate or a town climate. A forest may best be considered as an instance of vegetation on a gigantic scale, as is evident from the low temperature of the ground under the trees, and the freshness of the air in summer, especially in the evening and at night-time, thus affording evidence of active radiation. In this case the forest would be a source of cold rather than of heat. But here we are simply dealing with suppositions.

"From this point of view a forest is distinguished from all the other surfaces we have mentioned, in that it extends into a stratum of air lying far above that in which man lives and carries on all of his occupations which depend on

[1] "Om skogarnes inflytande på Sveriges klimat." From *Quart. Journal Roy. Met. Soc.* for April 1886, communicated by Mr. R. H. Scott, F.R.S.

[2] The forests dealt with were entirely of pines and firs.

climate, such as agriculture, &c. It should follow from a this that wheth[illegible] or a defect of heat, the one or the other should, thanks to the winds, be communicated to a greater mass of air, and be less sensible in the stratum close to the ground. The thermic properties of other surfaces are more immediately available in the lower stratum, and consequently, from the practical point of view, exert a greater influence on the temperature of the earth and of its immediate vicinity.

"If, then, we confine our consideration to that which from the practical point of view is perhaps the most important, the influence of forests on the state of temperature in the stratum in which man generally lives, in so far as this can be determined in the ordinary way by thermometers, I think that our reply for this country (Sweden) will be less uncertain, and it is as follows:—

"In the districts of our country which are open and are cultivated, during the annual interval of cultivation, a forest lowers the temperature of air and soil during evenings and clear nights, restricting the period of daily insolation, and thereby checks vegetation.

"The other influences of forests on temperature are either so slight that they possess no practical importance, as, *e.g.*, the moderation of cold in winter, or else are of such a character that they elude the ordinary mode of observation by thermometers. Among the effects of this nature we may mention the well-known fact that forests afford shelter against cold and violent winds to vegetation which would suffer from these winds, or to objects whose temperature is higher than that of the environment, as for instance the human body. It is in this last respect that the Swedish saying is true, namely, that 'the forest is the poor man's cloak.' In certain cases it may also yield protection against the cold air or fog which on cold nights comes from districts in the vicinity which are visited by frost. The advantages on the score of temperature derivable from the forest may therefore be considered to resemble that obtainable from a wall, a palisade, a hedge, or any object of that nature.

"On the one hand a forest, where it is close at hand, offers mechanical protection against cold and violent winds. On the other hand, it does injury either by retaining the solar heat required by crops, or by lowering the temperature of the soil during clear nights, and thus favouring the development of hoar-frosts. At a distance forests have no sensible influence on the climate of Sweden.

"If we wish to put these results to a practical application, it is impossible to say in general whether one should, or even could, clear the forest without injuring agriculture. But it appears that as regards the temperature, if we disregard the utility of forests in other directions, we might make extensive clearances without any prejudice to agriculture. It is certainly not a mistake to say that our best cultivated districts are the freest from wood, nor is it a mere chance that the harvests are, on the whole, more sure in the open country than in the forest. In the event of a bad harvest it is, as I well know, the wooded districts which have suffered most. At the same time I must at once admit that these provinces are also influenced by other powerful physical factors, possibly even more active than forests, such as an elevated situation, a bad soil, the presence of swamps, &c. But nevertheless it appears to me, after all that has been said in the preceding pages, that the forest has some bearing on the subject.

"At the present day, the words spoken 130 years ago by Pastor P. Högström, and at that time member of the Swedish Academy, are very generally applicable, inasmuch as it has been found that cultivation can to a great extent remove from a district its tendency to hoar-frost; this same result has frequently been obtained by draining or by clearing the forests, particularly those of deciduous timber, where the fogs, especially those which bring on [illegible] appear to have their origin and their aliment. On the contrary, a pine forest is an excellent shelter against cold, especially when it can stand between the country and marshes or surrounding districts where the cold has its rise. If, however, the forest interferes with sunshine and with wind, it should be cleared. It results, therefore, that while in some districts the clearing of a forest has been beneficial in averting hoar-frost, in others the result has been directly the opposite."

RESULTS DEDUCED FROM THE MEASURES OF TERRESTRIAL MAGNETIC FORCE IN THE HORIZONTAL PLANE, AT THE ROYAL OBSERVATORY, GREENWICH, FROM 1841 *TO* 1876

SIR GEORGE AIRY has recently published a valuable and extensive series of diagrams representing the diurnal changes in the magnetic forces in the horizontal plane at Greenwich between 1841 and 1876. In an introduction, the ex-Astronomer-Royal gives a short statement of the circumstances under which the magnetic work was undertaken at Greenwich, and the various changes which have taken place. With regard to the curves here brought together he writes as follows:—

The form of the curves, and the position of the points on them corresponding to hours of solar time, leave no doubt that the diurnal inequality is due mainly—and, as far as I can judge, entirely—to the radiant heat of the sun; and, it would seem, not to its heat on the earth generally, but to its heat on points of the earth not very distant from the magnets. In the hot months of the year the curve, though far from circular, surrounds the central point in a form which, as viewed from that central point, never crosses itself, and is, generally speaking, usually symmetrical with regard to E. and W. But in the cold months the space included in the curve is much smaller, in many cases probably not one-fifth of what it is in the summer months; and the curve often crosses itself in the most bizarre fashion, with irregular loops at these crossings. In the summer months there is a certain degree of symmetry; but here is, constantly, a preponderance on the west side, which leads me to imagine that the magnetic effect of the sun's heat upon the sea is considerably greater than the effect on the land.

To obtain some numerical basis for a report which, though undoubtedly imperfect, may convey some ideas on this wonderful subject, I have adopted the following course. I have confined myself to the months of June and July as probably the two hottest, and the months of December and January as probably the two coldest. In each of the curves applying to these months I have laid down a system of rectangular co-ordinates corresponding to the Greenwich astronomical meridian, and the line at right angles to the meridian (the geographical E. and W.). The extreme north ordinate and the extreme south ordinate were measured, and their sum taken, and interpreted by a scale of measure formed in accordance with the theory of the instruments, and this interpretation forms the "range of meridian force in terms of the mean horizontal force." In the same manner, the "range of transversal force" is measured. As the time of each two-hourly or hourly result is marked on the curve, there is no difficulty in fixing approximately on the solar times corresponding to the extreme N. and S. values and the extreme E. and W. values mentioned above. These are all the elements of the magnetic record which are included in the table.

MOVEMENTS ON THE SUN'S SURFACE

M. A. BELOPOLSKY, of the Moscow Observatory, states in *Astronomische Nachrichten*, No. 2722, some considerations of much interest regarding the solar

rotation. They are based upon a hydrodynamical investigation by Dr. Jukowsky, showing that in a liquid globe of which the angular rate of rotation increases from centre to surface according to a certain law, superficial currents set from the poles towards the equator, but take the opposite direction if the rotation be accelerated from surface to centre. These theoretical deductions have been experimentally verified by M. Belopolsky. A new criterion is thereby furnished as to the fashion of the sun's internal rotation. For both Spörer and Carrington have recognised that the motion of spots in latitude tends, on the whole, poleward; while the closing in towards the equator, with the progress of each epoch of disturbance, of the zone in which spots, faculæ, and prominences chiefly manifest themselves, is a well-recognised feature of periodical solar activity. This zonal movement is held to depend upon currents at considerable depths, but the drift of individual spots upon surface-flow; hence the sun's system of circulation is such as to indicate, according to Jukowsky's theory, rotation accelerated towards the centre.

The cause of this inequality is found by M. Belopolsky in the non-homogeneous character of the solar globe. Assuming that the variations of its density conform to the law adopted by M. Roche for the terrestrial spheroid ($\rho = \rho_0 (1 - \beta r^2)$), it follows that gravity must attain a maximum at a certain depth below the surface (this depth, in the case of the earth, is 1/6th of the radius). Under these circumstances the rate of rotation and amount of polar compression of successive solar strata must vary with gravity, and in the same sense. It is, moreover, highly probable that gravity and angular velocity will attain a maximum simultaneously. The ensuing frictional acceleration of the superimposed slower-moving layers is so conditioned as to lead directly to a law of surface-rotation identical with the empirical formula arrived at by Spörer from observation solely ($\xi = \omega + a \cos \phi$).

The minimum period of rotation for an interior solar shell, computed according to the foregoing hypothesis, is 21·3 days; the longest observed period for any part of the superficial globe is 27·5 days The mean of the two (24·4 days) differs very little from the period of 24·5 days deduced by Hornstein from magnetic observations. It is pointed out that Faye's *rationale* of the peculiar character of the sun's rotation implies for an inner nucleus the improbably short period of 2·2 to 3 days.

EDUCATION IN THE UNITED STATES[1]

THE work of education in the United States of America, as delineated in the Commissioner's report, is making steady progress and keeping pace with the great increase of population in that country, where are 266 cities with an average of 40,000 inhabitants, and a lowest limit of 7500. Various States are able to perceive that a more efficient course of education provided in them for the next generation is one of the greatest attractions to those earnest striving settlers who are the backbone of a growing country; and money and energy in increasing amounts are devoted to the purpose. The successful guidance of these powers to desired results depends largely upon the selection of capable district superintendents who will provide for the more careful selection and improvement also of teachers, and introduce the best methods and the best facilities of instruction; thus making common to the many what would have been confined to the extra intelligent few. The first use, therefore, to be made of liberal money votes is the provision of high-class inspectors, who can be secured only by higher salaries. One important duty of these officers arises from the system of establishing schools in every district being so perfect in all of the United States, that in Connecticut, for example, there are 158 school districts which have less than eight scholars in attendance during the year, and one case is quoted, not as being by any means unparalleled, of a school having only four scholars during the year, and for three months having one only, whose education consequently cost the district 60 dollars. In such circumstances the State inspectors can recommend the consolidation of several of these school districts into one. Where this cannot be done, it is not likely that an efficient, qualified teacher can be secured for each. Yet rather than this scattered population should grow up half taught, the New York superintendent of popular instruction recommends that a sufficient salary shall be made good out of State or general Government funds. It is the more necessary to meet this difficulty as population is not everywhere increasing. In Maine, for example, population has decreased, and the number of school districts has been reduced already.

In Massachusetts a greater number of scholars than the whole number of the school population (from 5 years of age to 15) were enrolled; but, on the other hand, Maryland and Virginia showed only 28 and 29½ per cent. attending, and what reports could be gained from Louisiana showed only 19 per cent. enrolled, and not above 13 per cent. attending. Of course, in such a State, there is the double difficulty of getting the coloured population to school and of raising the money to pay for it; poverty standing in the way of fair remuneration of teachers as much as the lazy ignorance of the blacks in that of regular attendance. Naturally half-day sessions have suggested themselves as being economical in every way, requiring only half the staff of teachers, and half the schools and school-furniture. But a danger in this system is lest the teacher should be overworked; and, where he is able to do so greatly increased work, it is fairly recommended that his salary should be increased accordingly. A great variety of work therefore presents itself to the inspectors, and much discretion and knowledge will be required to meet all emergencies.

It is easy to see that no New World organisations or ambitions are any match for the evils of population bred down to the point of a hard struggle for existence. These evils are developing in America as fast as they did in ancient cities. Truancy is increasing, and many children never attend school even in such a city as Providence, R.I. New York experience acquits employers of labour of any mischievous influence in the matter. It is curious to note that while in England charitable funds have been diverted gradually to the education of the more promising children, and School Boards have had intrusted to them the unpromising residuum, in American great cities the public schools take in all the former, while the benevolent are urged to take up the work of teaching the latter, for whom the regular course is too advanced. Free education, approved by certain States, can be more easily adopted in such a state of things, where the large ratepayers get large advantages, than in a country like ours, where payment made and advantage to be gained would be in exactly inverse ratio.

A very large proportion of the pupils in the primary schools are of the ages of 8 and 9, and the number who pass on to the secondary schools is about 40 per cent.; but not 1 in 12 of these reaches the higher standards of the secondary schools. Since also 60 per cent. never get beyond the elementary schools, the report urges how needful it is that the education given in these schools should be as complete in itself as possible, and not merely a preparatory step towards the "grammar" or secondary studies. The different proportions of arithmetic required in the different cases will force this upon the mind at once. Elsewhere in the report it is taken as an accepted rule that more cultivated fitness is required to teach a primary than a model school.

[1] "Report of the Commissioner of Education for the Year 1883-84." (Washington, Government Printing Office, 1885.)

The number of females attending the second-grade schools is equal to the number of males, and three-fifths of the teachers also in these schools are women. So many important institutions having for their main object the higher education of the sex have been opened in the United States that it is considered that the special examinations of females conducted for some time past under the auspices of the Harvard University may now be dropped. The number of them competing for scholastic honours on the same basis as the men is steadily increasing; "but," the report suggestively adds, "not rapidly enough to threaten any disturbance of existing social, domestic, or business relations."

One association for promoting the higher education of women reports that while the physique of lady students is higher than among women at large, yet that even that of the former is painfully low, and requires that measures should be taken against so dangerous a deterioration.

With regard to the co-education of men with women, a committee, appointed by a Western College to inquire into the subject, conclude by saying:—

"Joint education of men with women in the higher studies has now been tried in a sufficient number and variety of colleges, and for a sufficient length of time to prove that no special difficulties and evils grow out of it, and that it does away with the greatest difficulties and evils of the old monastic system. It makes college life and society more nearly human instead of only 'half-human.' The half-human ever verges first and last towards the bestial, whether in armies, on shipboard, in miners' camps, or in colleges, monasteries, or nunneries. It would be wise to humanise the colleges still more, rather than to begin the process of dehumanising them."

It is then urged that all lectures and studies should be conducted in as public a manner as possible, and attended by friends and relations of both sexes.

Kindergarten teaching is being carried out more largely, but is making its way more as a charitable institution than as a branch of education. Very appropriately it is becoming the ladies' charity; its work is found specially beneficial as the early beginning of a reformatory education for the purpose of overcoming inherited vicious propensities and physical infirmities. Most energetic efforts for this purpose are being made at San Francisco in particular.

Attention is specially called in this report to the desirability of teaching history so as to make the reading of it an intelligent study, attractive to its learners, who will fill up leisure time with its pursuit instead of, as of old, insisting on the laying to heart long tables of dates and dry facts, "killing the life out of the subject, disgusting the pupils, and giving them a dislike for historical reading."

Colleges of the highest class keep increasing in number, yet, nevertheless, the totals of teachers and pupils are small for the proud name each claims of "University." Some have resigned that title and devoted themselves to school work; but more fresh ones have sprung up which constitute a splendid force for future generations when their work, their wealth, and the population supporting them, have been multiplied. The fact of a superabundance of such institutions proves how highly learning even of the least utilitarian character is esteemed.

Perhaps traceably to temporary reasons, classics seem to be gaining rather than losing ground upon physical science at Harvard, a higher standard of instruction and attainment having been required in the latter. Technical schools, however, make steady, though not rapid, progress. Agriculture, mining, and building form so large a proportion of American employment that full attention can be given to these subjects with little hesitation. The bulk of their pupils are at once absorbed in further teaching, instead of putting into practice what they know, with their own hands.

The United States Commissioner of Education takes an annual survey of the whole educational world, and presents it to all who study his report, and when the subjects to be taught a different people like the 200,000,000 of British India are in it placed side by side with those which seem important in our own schools, a question suggests itself whether scientific teachings have not a better claim than the old knowledge to the title of "literæ humaniores." We see how local and confined are classical and historical studies, and of what common value to the whole human race are the elements of natural and physical science.

The free education which Texas and others of the United States are in favour of is not recommended by our Commissioners even in a country where it would interfere with so few vested interests as in India.

We are glad to know that a work on public libraries is progressing, which is intended to supplement the special report published in 1876.

There are 11,663 institutions in regular correspondence with the Bureau, and no one reading this report can fail to see the importance of a common centre of communication to so many and so various efforts to carry on the great work that will have such an influence over the next generation. A central nucleus, again, to this organisation must be a library, by reference to which inquiries from so many quarters on so many subjects may be answered. It is hard, therefore, to believe it a wise economy of a great nation to cut down the allowance for so permanent a part of the office as this from 1000 dollars to 500 dollars, which, nevertheless, has been done.

W. ODELL

COLLECTION OF HAIRS AFTER EARTHQUAKES IN CHINA

IN Dr. Macgowan's "Note on Earthquakes in China," republished in NATURE for May 6 (p. 17), I find the following passage:—

"The tremors that are experienced in Chehkiang, Kiangsu, and coterminous regions to the west, are sometimes followed by the appearance on the ground of substances that in Chinese books are styled 'white hairs.' When I first called attention to records of that kind that are found in local gazetteers, I suggested that they might be crystals precipitated by gaseous emissions, such as were once reported as occurring after an earthquake in south-west of the United States; from later descriptions of these 'horsetail-like' substances I incline to the opinion that they are organic, perhaps mycelium."

I think there can be little doubt that Dr. Macgowan's conclusion is well founded, and that the "white hairs" have no real connection with the earthquake.

In 1852, during one of the late Mr. Fortune's visits to China, he experienced the shock of an earthquake at Shanghai. He gives the following curious account in "A Residence among the Chinese" (pp. 4, 5), of the subsequent search for the hairs:—

"Groups of Chinese were seen in the gardens, roadsides, and fields engaged in gathering hairs which are said to make their appearance on the surface of the ground after an earthquake takes place. This proceeding attracted a great deal of attention from some of the foreign residents in Shanghai, and the Chinese were closely examined upon the subject. Most of them fully believed that these hairs made their appearance only after an earthquake had occurred, but could give no satisfactory explanation of the phenomenon, while some, more wise than their neighbours, did not hesitate to affirm that they belonged to some huge subterraneous animal whose slightest shake was sufficient to move the world.

"I must confess, at the risk of being laughed at, that I was one of those who took an interest in this curious subject, and that I joined several groups who were

searching for these hairs. In the course of my travels I have ever found it unwise to laugh at what I conceived to be the prejudices of a people simply because I could not understand them. In this instance, however, I must confess the results were not worth the trouble I took. The hairs, such as I picked up, and such as were shown me by the Chinese, had certainly been produced above the earth and not below it. In some instances they might readily be traced to horses, dogs, and cats, while in others they were evidently of vegetable origin. The north-eastern part of China produces a very valuable tree known by the name of the hemp-palm [*Chamærops Fortunei*, see Kew Report, 1880, p. 31], from the quantity of fibrous bracts it produces just under its blossoms. Many of these fibres were shown to me by the Chinese as a portion of the hairs in question; and when I pointed out the source from which such had come, and which it was impossible to dispute, my friends laughed, and, with true Chinese politeness, acknowledged I was right, and yet I have no doubt they still held their former opinions concerning the origin of such hairs. The whole matter simply resolves itself into this: if the hairs pointed out to me were the *true* ones, then such things may be gathered not only after earthquakes, but at any other time. But if, after all, these were not the real things, and if some vegetable (I shall not say animal) production was formed, owing to the peculiar condition of the atmosphere and from other causes, I can only say that such production did not come under my observation."[1]

W. T. THISELTON DYER

THE U.S. GEOLOGICAL SURVEY

THE American papers contain an announcement which will be received with some astonishment in Europe. A member of Congress, Mr. Herbert, of Alabama, has introduced a Bill into the House prohibiting the Geological Survey of the United States from expending any money for palæontological work, except for the collection, classification, and proper care of fossils and other material; and from composing, compiling, or preparing for publication monographs, bulletins, or other books except an annual report containing merely the transactions of the bureau and other routine official matter. It is further proposed to sell off the laboratories and other property of the Survey which after the passing of the Act would be no longer needed. Of course there may be official or departmental reasons for reorganisation or retrenchment of which the outside world is ignorant. But these reasons must be very serious indeed to justify such action as is proposed. If there is one scientific undertaking of which the United States have pre-eminently just reason to boast as a model to all civilised countries, it is their Geological Survey. For completeness of equipment it has no rival in the world, and already though it has only been seven years in existence its work both for excellence and amount has placed it in the very front of the scientific organisations of the time. Whether we look to its purely scientific achievements or to the importance of its practical work in mining and other economical departments, the crippling of the resources of the Geological Survey of the United States would be a calamity against which not only all lovers of science but all who are interested in the continued development of the natural productions of the great republic would energetically protest. We can hardly suppose that Mr. Herbert will have many supporters, and it is difficult to conceive from what possible motive he is acting. He calculates that if his Bill passes he will effect a saving of 250,000 dollars. He should try to find some branch of the public service where economy and retrenchment could be practised without seriously injuring the scientific credit and industrial progress of his country. And no doubt he could succeed in this search.

[1] "During a recent visit to the North-West Provinces of India, where earthquakes are not unfrequent, I could find no traditions such as that I have alluded to."

THE ROYAL SOCIETY SOIRÉE

THE President and Council of the Royal Society are to be entirely congratulated on the success of the reunion at Burlington House on the 12th inst. It was generally felt that the display of objects of interest was finer than any brought together for some years, and the general satisfaction expressed must have amply rewarded those upon whom the burden of the arrangements had fallen.

It is a little hazardous to say which was the most interesting object; but as an *actualité* the unpaired parietal eye of Sphenodon exhibited by Mr. Baldwin Spencer, fully described in last week's NATURE, perhaps bore the palm.

Next in biological interest came an exhibit by Mr. W. H. Caldwell including a complete series of the Ceratodus from the unsegmented egg to hatching. The complete exhibit illustrated early stages in development of the Monotremata—Ornithorhynchus and Echidna, the Dipnoid Ceratodus and some marsupial genera. The series were as follows:—

(1) Series of early stages of Ornithorhynchus, from a few hours after fertilisation to the newly-laid egg, of about the stage of a 36-hour chick; (2) series of early stages of Echidna, from just before laying to the newly-hatched fœtus; (3) various stages of young Echidna, from hatching up to 5 inches long; (4) complete series of Ceratodus, from the unsegmented egg to hatching; (5) stages of young Ceratodus after hatching; (6) series of about thirty stages, from segmenting egg up to birth of *Phascolarctos cinereus*; (7) ditto of *Halmaturus rufus*; (8) Specimens showing the arrangement of the embryonic membranes in *Macropus major*.

There were two exhibits of micro-organisms—one of micro-photographs of Bacteria, and another of certain micro-organisms themselves—by Mr. Cheshire. The former included enlargements, from negatives obtained with an oil immersion $\frac{1}{25}$ inch, of the following:—

Anthrax-bacillus, in tissue-sections and cultivations; hay-bacillus; bacillus of malignant œdema; micrococcus of pneumonia; tubercle-bacillus; bacillus of foul brood; *Bacillus megatherium*; *Clostridium polymyxa*; microbe of chicken cholera; comma-bacilli of Koch, Lewis, and Tinkler; Bacteria of putrefaction.

Mr. Cheshire exhibited (1) *Bacillus alvei* in sporulation; (2) *Bacillus alvei* spores in chain; and (3) spermatozoa of Apis forming in flocculent masses for packing in spermatophore.

Preparations illustrating the histological structure of the secretory tissues of certain plants, in which the substances secreted are of economic importance, were exhibited by Mr. W. Gardiner. Among these were hairs of leaf of *Flemingia Grahamiana*—wurras dye; laticiferous vessels of the stem of *Manihot Glaziovii*—ceara rubber; glands of the leaf of *Cinnamomum Camphora*—camphor.

In connection with biological inquiry may be specially mentioned Mr. Frank Crisp's demonstration of a new microscopic object-glass, by Prof. Abbe of Jena, an exhibit rich in hope not only for the future of microscopy, but also for astronomy. Eight of the ten lenses of this objective are made of a new kind of optical glass, composed of phosphates and borates without silex. The glass hitherto used contains as essential components only six chemical elements, while the new objective contains not less than fourteen. The secondary spectrum is by this means entirely removed, and only a small tertiary spectrum remains. The improvement in definition is especially marked

in the case of Bacteria and other minute micro-organisms.

As representing this last-named science we may specially mention a magnificent collection of the photographs of sun, stars, and planets which have recently astonished and delighted astronomers. The collection included specimens of the results recently obtained by Dr. Janssen, the Brothers Henry, Mr. Common, and Dr. Gill. Among these the star-photographs by the Brothers Henry, a photograph of a sunspot by Dr. Janssen, in which the minute structure of the penumbra and bridges of a large sunspot were exquisitely shown on a scale of something like 10 feet to the solar diameter, and two exquisite photographs of Saturn, enlarged eleven times by the Brothers Henry, excited the greatest wonder.

The Solar Physics Committee sent a collection of the daily solar photographs which they are now obtaining from India and the Mauritius to supplement the Greenwich series. These photographs are on scales of 12 inches or 8 inches to the solar diameter.

Mr. Norman Lockyer exhibited some photographs of spot spectra showing the widening of the lines and the reversal of H and K; and also some photographs illustrating the first results of a new branch of work recently undertaken at South Kensington, in which it is hoped eventually to obtain photographs of the spectrum of the chromosphere and prominences without an eclipse. The photographs showed that the bright lines H and K have already been caught. Mr. Lockyer also exhibited the new split-grating spectroscope recently described at the Royal Society; the green line of thallium or the red line of lithium being shown between the D lines.

Nor must we forget to mention a selection of drawings of the sun on a large scale from those now daily made at Stonyhurst College Observatory; these were exhibited by the Rev. S. J. Perry. Special care has been devoted to the faculæ, which are drawn with a red pencil, and their position is as accurately determined as that of the spots.

Mr. Howard Grubb exhibited a model of an equatorial and observatory which he has proposed for the 3-feet refractor for the Lick Observatory. All the required motions of the telescope, dome, and rising floor are effected by water-power (represented here by clockwork) governed by an electrical arrangement, the commutator being portable and carried by observer. By this arrangement the necessity of assistants, even in case of the largest sized instrument, is obviated, and the observer himself can, from any part of the Observatory, control all the motions of instrument and dome without using any physical exertion.

Even observatory clocks were not neglected. Dr. Leonard Waldo, of Yale College, U.S., exhibited a gravity escapement adapted for use in a precision clock, in which the escapement lifts the gravity arms with a gradually-increasing velocity, and with more certainty than in the ordinary forms; and a new astronomical clock.

Finally the Eclipse Committee of the Royal Society were represented by charts of the West Indies and of the Island of Grenada, showing the path of the total eclipse of August next, arrangements to observe which are now being made.

In pure physics the *pièce de résistance* was the colour photometer, for comparing the luminosity of colours and for testing the perception of colour, exhibited by Capt. W. de W. Abney, and Major-General Festing. The form exhibited was an improvement upon the original one, which was fully described in NATURE a little time ago.

Two exhibits by Mr. A. Stroh, also optical, may next be referred to. The first was an apparatus for showing stereoscopic effects on a screen; the next was an instrument for enlarging the angular division by means of reflectors, and thereby causing an object to be seen in exaggerated relief.

Electrical science was represented by the following new electrical apparatus, exhibited by the Electrical Power Storage Company: (1) various types of cells; (2) ring contact switches; (3) automatic switch, for closing the circuit when the dynamo is running at the required speed, and for breaking it in case of accident; (4) hydrometers, specially for use with the Company's cells; (5) pocket voltmeter for cell-testing; (6) automatic switch to cut out two or more cells when dynamo is started to keep constant electromotive force on lamps.

In addition to these there were the following, contributed by Messrs. Woodhouse and Rawson:—

(1) Assortment of incandescent lamps, showing the latest developments in connection with the manufacture of incandescent lamps. (2) Small arc lamp, giving 200 to 300 c.p. or more if required: specially designed for being connected upon the same circuit with incandescent lamps of ordinary c.p., and being run by the same dynamo. These lamps can be also wound for running in series. (3) Switch-boards, illustrating the universal system introduced by Messrs. Woodhouse and Rawson. (4) Electric-lighting switches and safety-junctions, for manipulating currents of from 200 to 500 amperes and upwards.

Mr. Pitkin exhibited some very interesting portable electric lamps intended for use in coal-mines and powder-magazines. A small teak box contains three or more accumulator-cells, which, when charged, give a continuous light for ten hours. In a modified form of the invention the lamp is detached from the box containing the accumulators, and is electrically connected to it by means of a flexible cord; by this arrangement a very convenient railway reading lamp is formed, as the box can be placed under the seat or on the rack, and the lamp itself either held in the hand, or hooked to the back cushions or to the button-hole of the coat of the reader in a convenient manner.

A new electrical influence-machine, having eight disks working within a glass case, was exhibited by Mr. Wimshurst.

Electricity applied to meteorology was represented by an electrical wind-vane and indicator exhibited by Mr. F. M. Rogers. This instrument enables the direction of the wind to be ascertained at any moment, and at any reasonable distance from the vane, within a house, observatory, or office. One vane will actuate several receivers, which are quite independent of each other. Should the vane remain for many hours upon any one point no waste of current takes place; the expenditure of such being limited to the momentary impulse required to effect change of direction upon the dial of receiver.

Messrs. de la Rue and Hugo Müller showed how the chloride of silver battery could be applied to electric lighting by a quantity arrangement. Instead of using a solution of chloride of ammonium simply, the solution, containing 2½ per cent. salt, is converted into a vegetable jelly, by dissolving in it Ceylon moss (Agar-Agar) to make a stiff jelly; this supports the zinc plate. The chloride of silver in *powder* is spread evenly on the bottom of the dish on which a piece of silver foil is placed.

One of the most interesting exhibits was by Mr. Conrad Cooke, C.E., who showed Dr. Auer von Weisegg's incandescence system of burning gas. A small Bunsen flame burning about 2½ feet of gas per hour gave a dazzling light of about twenty candles by suspending in it a gauze cylinder which had been impregnated with the salt of a rare earth (probably zirconium). Tested by the spectroscope, the light showed a large excess of blue rays as compared with an ordinary gas-flame.

Voltaic cells with solid electrolytes were exhibited by Mr. Shelford Bidwell.

Great excitement was caused among the chemists by the specimens of the new element germanium and some

of its compounds, from Prof. Winkler, of Freiberg, brought by Dr. Hugo Müller. These were :—

(1) Metallic germanium ; (2) germanium monosulphide, GeS ; (3) germanium disulphide, GeS_2 ; (4) crystallised germanium, obtained by the action of hydrogen on germanium sulphide.

Germanium is claimed to be the ekasilicium predicted by Mendeléeff in his periodic law.

	Mendeléeff's ekasilicium		Germanium
Sp. Gr.	5·5	...	5·469
Atom. weight ...	72	..	72·75
Atom. val.	13	...	13·3

Mr. G. J. Symons exhibited a small pocket thermometer as constructed by Immisch. This thermometer is actuated by a minute Bourdon tube. It is shaped like a watch, is water-tight, and nearly unbreakable.

A terrestrial globe showing magnetic meridians for the epoch 1880, and general distribution of the secular change of the declination, made for the Hydrographic Department of the Admiralty, was exhibited by Staff-Commander Creak, R.N. The approximate positions of the foci of greatest secular change of the declination and vertical force—except for the Arctic and Antarctic zones—are also shown. A consideration of these foci shows the general angular motion of the north or marked end of a freely suspended needle as regards secular change.

The fact that our space is nearly exhausted, although we have only referred to about one-half of the exhibits, well indicates the care taken to make the *soirée* a success. In conclusion we refer as briefly as possible to some of the remainder :—

Jordan's photographic sunshine-recorder, with specimens of observations, exhibited by Mr. J. B. Jordan, of the Mineral Statistics Branch, Home Office.

Original geological map of the Orange Free State, and section of part of Cape Colony, by the late G. W. Stow (unpublished), exhibited by Prof. Rupert Jones, F.R.S.

Specimens of daily synchronous charts of the North Atlantic for the period of thirteen months, from August 1882 to August 1883 inclusive, now in the course of preparation by the Meteorological Office, exhibited by the Meteorological Council. The specimens show the meteorology of the North Atlantic on three summer and on three winter days.

New and interesting plants, exhibited by the Director of the Royal Gardens, Kew.

Nolls' apparatus for demonstrating secondary growth in thickness of stems ; Hopfe's Collectiones Phytomicrotomicæ, exhibited by Prof. Bayley Balfour, F.R.S.

Collection of stone-headed arms, implements, &c., from New Guinea, exhibited by Mr. H. B. Brady, F.R.S.

Diagrammatic sections showing the geological structure and physical features of parts of Arabia Petræa, and Palestine, exhibited by Prof. Edward Hull, F.R.S., Director of the Geological Survey of Ireland : (1) from the sea-coast at Askalan by Jerusalem to the Jordan Valley at Jericho ; (2) from the table-land of Southern Judæa—across the Dead Sea to the Plains of Moab ; (3) from the Gulf of Suez, near Tor, by the Mountains of Sinai, to the Plateau of Badiet et Tih

Apparatus for measuring the luminosity of leaves, invented and exhibited by Dr. Gorham, to show that the white light reflected from leaves can be measured in *cents.* of a circle by the novel use of a *gray ring*, and that by putting this luminosity in the form of an equation its equivalents in colour are discovered, which, when placed in sectors on a circular disk and rapidly rotated on a wheel, are seen to match the colour of the leaf from which the luminosity has been originally reflected.

Specimens of miners' electric lamp, invented and exhibited by Mr. Swan.

Dr. Sohlberg's celestial globe of glass ; Dr. Schmidt's tellurium ; cosmographic clocks for showing universal time ; contoured map of the English Lake District, constructed by Mr. Jordan ; enlarged original photographs taken by Mr. Joseph Thomson in his recent journey up the Niger ; replica of Frankfort globe, of date 1520 ; two large diagrams—(1) Roraima, British Guiana, by Mr. Im Thurn, (2) a similar formation in the north of Brazil, by Mr. Wells ; collection of minerals from summit of Mount Roraima, exhibited by the Royal Geographical Society.

NOTES

It is with much regret that we announce the death of Surgeon-Major T. Lewis, Medical Staff, Assistant Professor of Pathology in the Army Medical School at Netley. Within the last few weeks the Council of the Royal Society decided to recommend Dr. Lewis for their Fellowship, in recognition of the importance of his various contributions to science Dr. Lewis had only just reached the forty-fifth year of his age at the time of his death.

The death is announced of Dr. E. Linnemann, Professor of Chemistry at Prague, which occurred on April 27. Among his papers a letter was found addressed to the Vienna Academy of Sciences containing a communication on a new chemical metallic element called austrium (Aus). This new element was prepared by the late Prof. Linnemann from orthite of arendal. The spectrum of austrium shows two violet lines ; the wave-lengths were found to be, for Aus α, $\lambda = 416·5$, and for Aus β, $\lambda = 403·0$. According to a note made by Prof. F. Lippich, of Prague, who communicated Prof. Linnemann's letter last week to the Vienna Academy, three not yet identified lines—$\lambda = 415·56$, $\lambda = 416·08$, and $\lambda = 416·47$—are shown in Ångström's atlas of the normal spectrum of the sun in the neighbourhood of the Aus α line ; the last of them might be supposed coincident with the Aus α line ($\lambda = 416·5$).

M. Chevreul, who on August 31 will be a centenarian, was on Monday afternoon presented by his colleagues of the Academy of Sciences with a bronze bust of himself, executed by Paul Dubois. Admiral Jurien de la Gravière, one of the senior members—his age being 73—made the presentation, and warmly complimented M. Chevreul on his long and distinguished career, which made France proud of him and of herself. M. Chevreul, who was much affected, made a brief acknowledgment of the honour done him.

The Swedish Academy of Sciences celebrated its centenary on April 5 last, having been founded by Gustavus III. on the eve of the French revolution.

The paper to be read at the ordinary meeting of the Society of Arts on May 26 will be "The Purification of Water by Agitation with Iron, and Sand Filtration," by William Anderson, M.Inst.C.E. On Tuesday, May 25, a paper on "Cyprus since the British Occupation," will be read by G. Gordon Hake, before the Foreign and Colonial Section. In the Indian Section, Capt. Richard Carnac Temple's paper on "Every-day Life of Indian Women, as Revealed in their own Sayings," will be read on May 21.

William Landsborough, whose name is known in connection with Australian exploration, died at Caloundra, near Brisbane, on March 15. His father was a Scottish naturalist of note. Having gone to Australia, Landsborough in 1860 discovered the head of the Thompson River, and in the following year traced the Gregory and Herbert Rivers to their sources. He then undertook to lead the expedition in search of Burke and Wills, and traversed the continent from the Gulf of Carpentaria to Melbourne. Subsequently he was appointed to a post in the public service of Queensland, and was voted 2000*l.* for his explorations in that colony.

A telegram from Catania of May 18 states that Mount Etna had been in eruption since 11 o'clock that morning. A very active discharge of vapour and cinders was proceeding from the western side of the central crater.

We are glad to learn of the formation of a Natural History Society at Yokohama. The marvel is that so long a time has been allowed to elapse before such a society was founded there or in Tokio, for probably there are no communities in the world in which the proportion of men of science is so high as here. But no doubt the local Asiatic Societies and the Seismological

Society absorbed much of the scientific work of the residents. The first meeting of the new Society was held at the beginning of last month, when Prof. Milne delivered a lecture on the geology of Japan, which is reported in full in the *Japan Weekly Mail* of April 3, and which is too comprehensive and detailed to lend itself to adequate treatment in a short note. We observe, however, that in speaking of the difference between the fauna of Yezo and of the other islands of the Japanese archipelago he suggests that the line between the two should be called Blakiston's line (from Capt. Blakiston, who first pointed it out), on the model of Wallace's line between the Javan and Australian fauna. Prof. Milne proposed this nomenclature a few years ago, and it is now adopted by some German publications. The difference, indeed, is not so great as that marked by Wallace's line, still it is of considerable importance. Thus in Japan we have the monkey, the sheep-faced antelope, the bear, and the pheasant; but on the other side of the straits the bear is a totally different one, the monkey, the pheasant, or the antelope is not found, and a totally different fauna exists. The suggestion of marking the dividing line with Capt. Blakiston's name is an appropriate one.

Dr. Trimen's Report for 1885 on the various botanic gardens in Ceylon, of which he is Director, is a very satisfactory document, as such reports from our colonial gardens generally are. It contains a considerable number of meteorological observations, and describes the arrangements made to carry out the scheme of a garden at Badulla, in the new province of Ceylon, for which funds have been voted. The usual report on the distribution of plants and seeds is given, and then comes a long list of additions to the collections of plants at the various gardens, which is followed by some interesting notes on economic plants and products. Under this head he makes various recommendations and suggestions which will no doubt be of the utmost value to perplexed planters who are assailed on all sides by dangers which are only too apparent, but which it requires scientific training and investigation to combat. Thus he advises that tea and cinchona should not be grown together, as it is only in such cases that the planter's scourge, *helopeltis*, does any appreciable damage to tea. On the other hand, he thinks that the diminution in the cultivation of cacao, through dread of *helopeltis*, is unreasonable, for the insect only attacks cacao grown in the open, and not that grown under the shade of trees, for example The Ceylon Herbarium has been arranged during the year in accordance with Dr. Trimen's "Systematic Catalogue of Ceylon Plants," and in the work of rearranging he was able to put together a series of notes describing about 280 additions to the flora of Ceylon, and 40 new species or varieties. That much yet remains to be done is obvious from the fact that during 1885 fifteen additional have been discovered in the island, many of which are striking plants. The Government has approved the formation of an exhibition containing specimens of the plants, grains, &c., of the island. Like many other colonial officials, Dr. Trimen has been busy during the past year preparing for the Colonial and Indian Exhibition, where the series of woods in the Ceylon section was prepared by him.

According to a letter received from Baron Schwerin, the well-known Swedish geographer, who is at present on a scientific mission to the Congo for his Government, he observed the great November meteor-stream on the 27th of that month, at 8 p.m., off Cape Palmas, on the Guinea coast (lat. 4° 29′ 9″ N., and long. 7° 44′ 16″ W.). He describes it as the most magnificent spectacle he ever beheld, "the whole sky being furrowed from nearly north to south by falling stars, looking like gigantic fireworks, in which thousands of 'star-rockets' were burnt off."

On the evening of April 27 a bolide was observed in several parts of the north-western provinces of Russia. A large ball of bluish colour was moving from south to north; in about two seconds it changed its colour into a bright electric-white, and suddenly broke in many pieces and disappeared.

In consequence of the ice breaking on the Volga, a considerable number of naphtha-barges were wrecked this spring, and about 2,000,000 poods, or 33,000 tons, of naphtha are now floating along the river. According to the observation of past years the presence of such a large amount of hydrocarbon in the water will produce a very disastrous effect upon Russian fisheries, not only along the Volga, but even on the northern coast of the Caspian Sea.

The tendency amongst modern Oriental scholars is to trace the origin of Chinese arts, sciences, and civilisation to Babylonia. The theory, however, is not accepted by many of the most eminent Chinese scholars. In the last number of the *China Review*, Dr. Edkins of Pekin gives his reasons for assigning a Babylonian origin to Chinese astronomy and astrology. Amongst these are the following:—Both peoples divided our day and night into twelve hours; the sun-dial is a Babylonian invention, and reached China at a very early date; the intercalary month belonged to the Accadians, and is found in the first sections of the Chinese Book of History. Geminus states that it was the dwellers on the Euphrates who discovered that, after 223 lunations or eighteen years, eclipses of the moon recur in the same order. The early use of the intercalary month by the Chinese implies that either they, or those from whom they derived it, knew this fact about lunations. Early Chinese astronomy, Dr. Edkins thinks, is too good to come from the Chinese of those days, and, on various learned grounds which he states, he concludes that the double hour, the astrolabe, the dial, the intercalary month, and the knowledge of the length of the year were all communicated from Babylon to China at different periods by land or by sea between about B.C. 2200 and B.C. 820.

The invitation to Norwegian sea-captains to make barometrical observations during the eclipse next August was not issued by the Norwegian Meteorological Society but by our Norwegian contemporary *Naturen*, to which the returns are also to be sent.

Messrs. Whittaker and Co., and Messrs. Bell announce in their new "Series of Hand-Books for Practical Engineers" Dr. Jul. Maier's book on "Arc and Glow Lamps." It will be a complete hand-book on the subject, especially relating to its practical applications, giving the latest results and improvements. The next volume in the same series will be Mr. Gisbert Kapp's "Electric Transmission of Energy," which is promised early next week. Mr. William Anderson has revised and added some new matter to his "Lectures on the Conversion of Heat into Work," which excited much attention when delivered last year at the Society of Arts. They will be published in book form by Messrs. Whittaker and Co.

The additions to the Zoological Society's Gardens during the past week include two Shaw's Gerbilles (*Gerbillus shawi*) from North Africa, presented by Mr. W. R. Ogilvie Grant; two Black-backed Jackals (*Canis mesomelas*) from South Africa, presented by Mr. F. Mosenthal; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. T. P. Lymn; a Brown Condor (*Sarcorhamphus æquatorialis*) from Chili, presented by Mr. R. J. James; two Red Kangaroos (*Macropus rufus*) from Australia, two Grey Parrots (*Psittacus erithacus*) from West Africa, an Indian Rat Snake (*Ptyas mucosa*) from India, a Green Lizard (*Lacerta viridis*), European, deposited; an Indian Coucal (*Centropus rufipennis*) from India, an African Tantalus (*Pseudotantalus ibis*) from West Africa, four Black-tailed Godwits (*Limosa ægocephala*), European, a Spotted Eagle Owl (*Bubo maculosus*) from South Africa, purchased; an Eland (*Oreas canna*), four Chilian Pintails (*Dafila spinicauda*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE BINARY STAR α CENTAURI.—Mr. E. B. Powell, to whose observations and calculations we are largely indebted for our present knowledge of the orbit of this celebrated binary, has recently published new elements giving the period as 87·438 years, the time of periastron passage at 1875·447, and eccentricity = 0·544. These elements appear to satisfy fairly the recorded equatorial measures made from 1834 to 1885 (as well as most of the ancient observations), with which Mr. Powell has compared them; but all the available observations have not been used—for instance, the Sydney measures subsequent to 1877 have been omitted, as some influence appears to have operated to throw out these measures from accord with those taken at other observatories. Mr. Powell considers that the evidence is tolerably strong against the period of α Centauri being only some seventy-six years (as given by the Downing-Elkin orbit), but thinks that in six or eight years, if careful measures be taken, the point will be settled as to whether the period is about seventy-six years or exceeds eighty-six years.

A NEW BELGIAN OBSERVATORY.—The Cointe Observatory, attached to the University of Liége, has been founded at the instigation of M. Folie for the purpose of affording instruction to the students in astronomy and geodesy, as well as of furnishing original observations. M. Folie is Director of this Observatory, as well as of the Royal Observatory at Brussels. The Cointe Observatory is furnished with a meridian circle by Cooke, the object-glass of the telescope of which is of 6 inches aperture, and the circle 0·8 metre in diameter. The Observatory also possesses a 10-inch refractor by Cooke, of the optical qualities of which M. Folie speaks in the highest terms. The astronomers attached to this institution are MM. L. de Ball and P. Ubaghs, the former of whom observes with the 10-inch equatorial, and the latter with the meridian circle. The Observatory is destined, we hope, to do good work in both these departments of astronomy.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 MAY 23–29

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 23

Sun rises, 3h. 59m.; souths, 11h. 56m. 29·6s.; sets, 19h. 54m.; decl. on meridian, 20° 37′ N.: Sidereal Time at Sunset, 11h. 59m.

Moon (at Last Quarter on May 25) rises, 23h. 33m.*; souths, 4h. 8m.; sets, 8h. 48m.; decl. on meridian, 16° 38′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury	3 25	10 37	17 49	13 12 N.
Venus	2 35	9 4	15 33	5 4 N.
Mars	12 10	18 54	1 38*	7 54 N.
Jupiter	13 24	19 42	2 0*	2 53 N.
Saturn	6 13	14 25	22 37	22 48 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

May	h.	
23	20	Jupiter stationary.
29	13	Venus at greatest distance from the Sun.

Variable Stars

Star	R.A.	Decl.			
	h. m.	° ′		h. m.	
U Cephei	0 52·2	81 16 N.	May 25,	3 18	*m*
U Monocerotis	7 25·4	9 32 S.	,, 28,		*M*
U Ophiuchi	17 10·8	1 20 N.	,, 26,	2 16	*m*
			,, 26,	22 24	*m*
X Sagittarii	17 40·6	27 47 S.	,, 26,	2 25	*m*
			,, 29,	0 0	*M*
U Sagittarii	18 25·2	19 12 S.	,, 26,	2 25	*M*
			,, 29,	21 40	*m*
β Lyræ	18 45·9	33 14 N.	,, 28,	21 30	*m*
R Lyræ	18 51·9	43 48 N.	,, 28,		*m*

M signifies maximum; *m* minimum.

Meteor Showers

The *Draconids*, radiant R.A. 280°, Decl. 54° N., and the *Cygnids*, R.A. 301°, Decl. 37° N., are due this week. Meteors from radiants near α Ursæ Majoris, R.A. 175°, Decl. 64° N.; in Lyra, R.A. 273°, Decl. 34° N.; and in Lacerta, R.A. 329°, Decl. 48° N., have also been observed at this season.

GEOGRAPHICAL NOTES

THE Kermadec Islands, which have during the past week been occupied by the orders of the Home Government by Admiral Tryon, Commander-in-Chief on the Australian station, are a group of rocky islets about 600 miles to the north-north-east from the North Island of New Zealand, and lying on the steamer route from Christchurch or Wellington to Fiji. They are due east of Norfolk Island. The principal islands of the group are Raoul or Sunday Island, the position of which is put at 29° 12′ S. and 178° 15′ W. It is described as about 12 miles in circumference, rugged and very steep, without an anchorage. It is said to be covered with wood, and to be uninhabited except for a few white men, waifs and strays from the ocean, shipwrecked sailors, deserters, &c. The other islands of the group are Macauley, the Curtis Islands, Havre, and Espérance.

AT the last meeting of the Geographical Society of Paris a letter was read from M. Borelli, who is at present travelling in that part of Eastern Africa where M. Barral has been murdered. M. Brettes, referring to his explorations of the Grand Chaco between the Argentine Republic, Bolivia, Brazil, and Paraguay, said he had discovered a great salt lake which he proposed to call Lake Crevaux, and three rivers, hitherto unknown, the most important of which would be called Rio Lesseps. M. de la Grye stated the propositions adopted by the committee appointed to study the reforms necessary for the adoption of a common international orthography for maps. These were—(1) any change for European countries is recognised as impossible; (2) in Asia, Africa, and America it is proposed that the French *u* should be replaced by the diphthong *ou*, the value of the French vowels *a*, *e*, *i*, *o* remaining unaltered; (3) in the geography of the Far East the sound of the *u* with a diæresis is represented by *oe*, *g* and *l* are always hard, *ch* is reproduced by *sh*, amongst the gutturals the soft ones are represented by *gh*, the hard by *kh*; (4) as far as possible, by the aid of this common alphabet, the most generally used pronunciation of places, towns, rivers, mountains, &c., shall be reproduced. Prof. Ersler of Copenhagen described the results of his investigations into the cartography of Denmark from the time of Ptolemy.

THE French staff officers are busy with the continuation of the Paris meridian to Laghouat, about 4° south of Algiers. When this work is finished this line will be measured with precision from the Orkneys to this locality. The length determined will not be far from 30°, or about three times its original extension, which was 10°, from Dunkirk to Formentera.

TWO Finnish *savants*, Drs. Hammarström and Ehnberg, have just returned to Helsingfors from a scientific journey in Eastern Siberia and China, whence they bring valuable scientific collections.

NEWS received from Baron Schwerin, the Swedish scientific explorer on the Congo, informs us that he landed from the Liverpool steamer in December last at the mouth of the River Chiloango, whence he proceeded on foot through the districts of Cacongo and Cabinda to Banana. During the journey along the coast the Baron succeeded in making many valuable observations of the shore-lines or terraces on the gradually-rising coast, and of the effects of the tide on the plastic formation of the sandy fore-shore. He also paid special attention to the study of the great influence which ocean currents exercise on the direction of the flow of rivers in their lowest course.

COUNT SAMUEL TELEKY is organising, at Pesth, an Expedition for the exploration of Central Africa; the fitting out will be completed by the end of May, and 100 well-armed men will reach Zanzibar in the course of June. Capt. Hähnel, of the Austrian Navy, will take part in the Expedition, and two boats will be taken out in pieces. It is believed here that the Expedition will not confine itself to scientific explorations only.

THE three numbers of the *Journal* of the Geographical Society of Tokio for last year which have been recently published do not contain much of special interest to English students of geography, although the papers could hardly fail to instruct a Japanese audience, which can hardly be expected to be as familiar with the colony of Victoria, or with the progress of Russia to the southward, as Western readers. The report of the Japanese delegate to the Prime Meridian Conference at Washington is also printed. Of special papers there are two: one on the Bonin Islands, called Ogasawarajima by the Japanese; another on the area within which Mount Fuji is visible.

THE IRON AND STEEL INSTITUTE

THE Iron and Steel Institute held its meeting on the 12th, 13th, and 14th inst., under the presidency of Dr. J. Percy, F.R.S., in the Theatre of the Institution of Civil Engineers.

The President made some introductory remarks having reference to the papers about to be read. He had strong hopes that, from a scientific point of view, great results were likely to flow from investigation of the microscopic structure of iron and steel, as it was only by physico-chemical investigation that our present ignorance of the causes of many phenomena relating to metal would be lessened or dispelled. He was peculiarly glad to read Mr. Turner's paper, as he had had the honour, when first addressing the Institute, of suggesting the solution of specific problems relating to iron and steel which had been ably attempted by the author; he should be glad to see medals or rewards conferred on those who solved problems emanating from the Institute. He made special reference to Mr. C. P. Clarke's paper, which we hope to print *in extenso*. He had great pleasure in drawing attention to Sir Henry Bessemer's gift to the Institute of a series of specimens illustrative of the process universally known by his name, which he exhibited at South Kensington some time ago. The President very shortly referred to what Sir Henry had done for metallurgy, and called upon the members to join in cordially thanking him for his gift to the Institute, which was done with acclamation.

With regard to the prevailing depression in trade, he thought over-production was the main cause of the evil in question. Considering the enormous power the iron and steel trades, for instance, possessed for production, it was not surprising that over-production should take place. Besides, what had taken place in our own country had also occurred to a greater or less extent in Germany, Belgium, France, Austria, Russia, and especially the United States of America

British workmen had a special enemy to contend against in the fierce competition from abroad, where men labour for less wages and work longer hours. He hoped that the problem would be solved, not by our countrymen having to be paid less for their labour, but by the labourers in foreign countries rising to our level, when our trades would have less to fear from foreign competition.

Passing from the over-production of iron and steel, the President referred to the fact that the surface of the earth was limited, whilst the human race was constantly increasing, and as the world could only sustain a certain population, so portions of it could do no more; he was of opinion that what was really at the bottom of the troubles of Ireland was the sentiment of Irishmen trying to live where they could not gain their livelihoods, when there were millions of acres in our colonies which they could cultivate and be happy upon. Shortly referring to the Colonial and Indian Exhibition, the speaker concluded, a vote of thanks for his address being moved by Sir Isaac Lowthian Bell and seconded by Sir Bernhard Samuelson.

The Bessemer Medal for the year was awarded to Mr. Edward Williams, who was unfortunately prevented by ill-health from coming to the meeting to receive it.

There was a very large number of papers on the agenda, some of which had to be deferred. Amongst the papers read and discussed some were important not only technically but scientifically. Mr. P. W. Flower's paper on the origin and progress of the manufacture of tin plates is hardly of this character, but it is interesting both from an archæological and industrial point of view. Aristotle, Pliny, the Phœnicians, Herodotus, and Diodorus Siculus have all made reference to this manufacture. In more modern days we find it flourishing in Bohemia in 1620, from which country Yarranton introduced it into England about 1665, thus fortunately succeeding in benefiting the iron trade of Wales and the tin trade of Cornwall, which were both much depressed. Later on, the use of coal instead of charcoal, of vitriol for pickling-purposes in place of barley-meal, of Siemens's soft steel for charcoal iron, of Bessemer steel in place of puddled bar, have all had their influence on this industry. Ninety-six works, with 320 mills in all, work up about half a million tons of British steel and iron annually into tin plates. The production last year was over 7,000,000 boxes, of which probably 3,000,000 were used in the manufacture of 875,000,000 of 1 lb. canisters. "By means of these canisters Europe receives largely of beef from the Western prairies, salmon (in shiploads) from Oregon, mutton from the plains of Australia, fruits of all sorts from California, lobsters from Boston and Nova Scotia, oysters and peaches from Baltimore, sardines and green peas from France, pine-apples from Mauritius, apricots from Lisbon, milk from Switzerland, jams from Tasmania, and many other products of foreign soil, which complete the list of what the French have called *conserves alimentaires*."

Mr. Hamilton Smith, jun., in his paper on wrought-iron conduit pipes, refers to the method of hydraulic mining introduced in California in 1852. It may roughly be defined as the discharge of jets of water, actuated by gravity with a considerable head, against a bank of auriferous gravel, the water acting first as an excavator, and afterwards as a carrier of the washed material. The supply of water for these jets was at first conducted through hose made of heavy cotton duck cloth, which was strengthened by outer nettings of cordage when the pressure was large. In 1853 an ingenious miner laid in his main a line of pipe consisting of joints of ordinary stove-pipe, made of very thin sheet-iron lightly fastened together with cold rivets; the joints being united stove-pipe fashion. This pipe answered admirably, and in a short time all the hydraulic gravel mines in California obtained the pressure for their water-jets by means of thin sheet-iron pipes. As a protection against rust, each joint is immersed for several minutes in a bath of boiling asphalte and coal-tar; a little rosin is added when a glassy surface is desired, and sometimes a little fish-oil. After successful practice in the mines had demonstrated the advantages and capabilities of wrought-iron pipes, they were used for permanent conduits both for conducting water to mining districts across deep mountain gorges, and also for the supply of cities. San Francisco, a place of some 300,000 inhabitants, receives its water through two lines of such pipes, and a third pipe, many miles in length, and of large diameter, is now being laid for an additional supply.

"On a Neutral Lining for Metallurgical Purposes" was the title of a paper in which M. Ferd. Gautier, after describing various linings of an acid, basic, reducing, and oxidising character, refers to one in which chrome iron is the main constituent. From a physical point of view chrome ore is essentially refractory; heated in lumps it does not crumble to pieces, however high the temperature. In general metallurgy, where no alkalies in notable quantities are present, chrome iron is a refractory material of a specially neutral character, since neither acids nor bases act upon it. The chrome iron is employed shaped in pieces, and also as a mortar in combination with lime. The use of this material in the basic open-hearth process has been kept secret for some time; it was exhibited last year at the International Inventions Exhibition.

The President's paper on steel wire of high tenacity referred to experiments on the tensile strength and chemical composition of wires of various thickness. The mechanical tests were made at the request of the author by Col. Maitland, R.A., and the analyses by Sir Frederick Abel. The wire was of a very pure character, there being a percentage of total carbon 0·828, manganese 0·587, silicon 0·143, sulphur 0·009, copper 0·030, without a trace of phosphorus. The tensile strengths of the wires increased as their thickness diminished, as shown by the following table:—

Diameter in fractions of an inch	Tensile strength in tons per sq. inch
0·093	154
0·132	115
0·159	100
0·191	90

The difficulty in accounting for the increase of strength with diminution of diameter in wire-drawing is the circumstance that the density of the material diminishes during this process.

Mr. T. Blair's paper on certain necessary products of blast-furnaces, and Mr. Bauerman's note on a rare blast-furnace slag of the composition of gehlenite, were discussed together.

The paper by Mr. John Head on blow-holes in open-hearth steel brought about a very animated discussion. The blow-holes in steel, the author explained, are due to the contraction of the metal on cooling, or to the presence of imprisoned gases in its mass. Those of the first kind are removed by welding, when the steel is subjected to pressure. Those of the second kind the author maintains to be similar to what is technically known as "seedy boil" in glass, and may be removed in the manufacture of steel by not allowing the flame to touch the fused metal, just in the same way as they have been

got rid of in the manufacture of glass by the use of the radiating furnace. It was suggested, in explanation of certain mysterious failures which had occurred in steel, the possibility that in these cases the gaseous blow-holes in an ingot may have sorted or arranged themselves in a series, thus forming a line of weakness in the plate or bar, which has failed along that line when subjected to a strain much below that which test-pieces from the same plate or bar would withstand. In conclusion the author had no doubt "that, by manufacturing open-hearth steel free from gaseous blow-holes, the metal produced would be much stronger and more reliable than that made by contact of flame, and the result would be a greater confidence in its use." In the discussion of this paper a unanimous verdict was given in favour of steel alike by representatives of the Admiralty, the Board of Trade, and Lloyd's Registry, who are the official judges of the metal, and by shipbuilders and boiler-makers who have found the material more trustworthy than the best iron. As regards the manufacturers, one acknowledged to the fact of there being a large difference in the total carbon, according as a sample was taken from one end or another of a large ingot, whilst another speaker had found the metal to be more regular if made in a radiation than a contact of flame furnace. As the author stated in his reply, the users were evidently even better satisfied with the material suoplied them than the makers, which is certainly a favourable sign.

Mr. F. W. Webb's paper on the endurance of steel rails added further testimony to what had already been said in favour of steel. In 1876 the London and North-Western Railway put down 31,391 tons of iron and steel rails together, twelve months after which iron rails entirely disappeared, whilst the estimated requirements for this year are only 11,600 tons. The small quantity of rails required for renewals account in some measure for the depression in the steel-making trade. On the other hand, if steel sleepers are found to answer, and the author sees no reason why they should not, 45,000 steel sleepers having been put down on the London and North-Western line, and giving every satisfaction, orders for steel sleepers should in great measure make up for want of orders for rails.

Dr. H. C. Sorby drew attention to the application of very high powers to the study of the microscopical structure of steel, having employed a power of 650 linear which, being about ten times that used in his previous researches, opened out a new field for research. The chief facts were best seen in the case of an ingot of steel of medium temper. On fracture, comparatively large crystals were visible, radiating from the surface to the interior. When a properly-prepared microscopical section was viewed with a moderate power, it was easy to see that, after having crystallised out from fusion at a high temperature, these large crystals broke up on further cooling into much smaller ones. What was now seen with very high powers was that these smaller crystals finally split up into alternating very thin plates. Taking all the facts into consideration, it appeared as though a stable compound of iron with a small amount of carbon existed at a high temperature, which at a lower broke up into iron combined with a larger amount of carbon, and into iron free from it. If these two products had not differed so much in hardness, or if the alternating plates had been considerably thinner, or if definite plates had not been formed, such a compound structure would never have been suspected. It has probably never been specially looked for in other substances, and might exist without being visible, even with the highest and best magnifying powers. To give a good idea of the size of the plates, he would refer to what was seen in a longitudinal section of medium steel forged from an ingot 3 inches in diameter down to a bar 1 inch square. When broken, it showed a very fine grain, and when a prepared section was examined with a moderate power, this grain was seen to be due to crystals often about 1/1000 inch in diameter, which were not drawn out or distorted, as they would have been if they had existed previously to final cooling after hammering, and as they were distorted if the steel were hammered at a lower temperature. Examined with a power of 650 linear, these crystals only 1/1000 inch diameter were seen to contain something like 60 of the alternating plates, and even this extremely delicate structure showed little or no trace of distortion. Of course it was impossible to separate and analyse such thin plates, and reliance must be had on induction to furnish a knowledge of their nature. His reason for concluding that the hard plates contained combined carbon was that they were not seen in iron free from carbon; they increased in amount with increase of carbon, and were seen to the greatest perfection when there was a considerable amount in a combined state.

Mr. Thomas Turner's paper on the constituents of cast-iron is an attempt now made for the first time to systematise in some measure our knowledge of the constituents generally present in cast-iron, to estimate the mechanical value of any given specimen of which the chemical analysis is known, and conversely, when any given mechanical properties are desired, to predict the most suitable composition for the material. In connection with this subject two opposite opinions have been advanced by different authorities, both of which found expression at the Glasgow meeting of the Institute. On the one hand, it was suggested that probably the best mechanical properties would be obtained in a cast-iron which contained if possible nothing but carbon and iron, all other elements being regarded as impurities. On the other hand, it was said that possibly very considerable quantities of other elements might be added, even upwards of 10 per cent., without rendering the metal unfitted for the founder's use. It might be, if chemically pure iron could be obtained, that the first suggestion would be correct, and possibly if the various constituents could be added in just such proportions as to neutralise each other's ill-effects, as under such circumstances they are capable of doing, then the second suggestion might likewise prove true. As a matter of fact, pure iron cannot be manufactured, and the ill-effects of large proportions of foreign substances cannot be neutralised. A cast-iron of tolerable purity can, however, be produced, from which, by variations in the proportions of the constant constituents, a metal of desired character may be prepared. The author treats in detail of the influence of carbon, manganese, phosphorus, silicon, and sulphur, all of which are invariably present in greater or less proportion. Of these, carbon is the most important constituent, and remarkable differences are produced by variations in the proportions of combined carbon and graphite. For the more ordinary cast-iron the amount of total carbon varies from about 3 to 3·8 per cent., a lower proportion being generally due to some irregularity in the working of the blast-furnace. The relative proportion of graphitic to combined carbon can only be affected in two ways—by difference in the methods of fusion after cooling, and by variations in the proportions of other elements present. Maximum general strength, that is, considerable crushing strength combined with high tensile strength, is obtained with not less than 0·4 per cent. of combined carbon, the metal being sufficiently soft to work with the tool; with more combined carbon the metal becomes harder, its crushing strength increases while the tensile diminishes. The amount of graphitic carbon depends upon the total and combined, but, in the majority of cases, 2·6 per cent. for crushing strength, 2·8 per cent. for general strength, and 3 per cent. for strength and softness, will be found best. It is to be remembered that any required proportion of combined carbon may be obtained by altering the amount of silicon on the one hand, or of manganese and sulphur on the other, the former diminishing and the latter increasing it. As regards silicon, the experiments show that, if high crushing strength is required, it can be obtained by a low percentage of silicon; if a high tensile strength is required the silicon should be somewhat higher, while for softness, smoothness of surface, and fluidity a still higher proportion is necessary. The author is of opinion that, although phosphorus is objectionable in wrought-iron and steel, it is not so in cast-iron, the specimens which possessed the highest average quality being all moderately phosphoric irons, averaging from 0·19 to 0·72 per cent., 0·3 per cent. being a very suitable average proportion for strong iron; the amount must be proportioned according to the object the founder has in view. A small quantity of sulphur is known to produce hard white iron, owing to an increase in the amount of combined carbon, acting therefore, when in small quantity, in a manner almost exactly opposite to that of silicon. Sulphur and silicon are to a considerable extent mutually exclusive of each other in cast-iron. Thus the addition of sulphur to siliceous iron causes the separation of graphitic matter containing silicon, while the addition of silicon to an iron rich in sulphur causes the separation of graphitic matter rich in sulphur, one part of sulphur neutralising the effect of from five to ten parts of silicon. From 0·2 to 0·75 per cent. of manganese appears to exercise no injurious effect in the majority of cases, and may even be beneficial. The author considers the following to be proved, that pure cast-iron, *i.e.* iron and carbon only, and cast iron containing excessive amounts of other constituents, would not be suitable

for foundry work; that the ill-effects of one constituent can at best be only imperfectly neutralised by the addition of another constituent; that there is a suitable proportion for each constituent present in cast-iron, depending upon the character of the product desired, and upon the proportion of other elements present; and that variations in the proportion of silicon afford a reliable and inexpensive means of producing a cast-iron of any required mechanical character which is possible with the material employed.

Krupp's hot-blast pyrometer, which was shortly described, consists of an arrangement by which the hot blast is drawn with a fixed proportion of cold air into a chamber, the temperature of which, being measured with an ordinary thermometer, gives that of the hot blast by calculation.

ON DISSOCIATION TEMPERATURES, WITH SPECIAL REFERENCE TO PYROTECHNICAL QUESTIONS[1]

IN bringing the subject of dissociation before the Royal Institution of Great Britain, the author proposed to confine himself to its influence on combustion and heating, that is to say, to its effects on combustible gases and the products of combustion, and on furnace work generally. His researches had been made for the most part in connection with large gas furnaces constructed according to his new system of working with radiated heat, or what may be otherwise called free development of flame. In the first or active stage of combustion the flame passed through a large combustion chamber (all contact with its surfaces being avoided), and parted with its heat by radiation only; while in its second stage the products of combustion were brought into direct contact with the surfaces and materials to be heated, by which means the remainder of its heat was abstracted. This, in a few words, was a description of the method of heating with free development of flame. In perfecting this system of furnace, the principle of which was in many respects the reverse of that generally accepted, both as regards construction and working, he had to examine into the accuracy of certain scientific theories which could not be brought into harmony with the actual results he obtained.

Adopting the generally-accepted theory of combustion, according to which a flame consists of a chemically-excited mixture of gases, whose particles are in violent motion, either oscillating to and from each other, or rotating around one another, it followed that any solid substance brought into contact with gases, thus agitated, must necessarily have an impeding effect on their motion. Motion being the primary condition of combustion, the latter would be more or less interfered with, according to the greater or less extent of the surfaces which impede the action of the particles forming the flame; in the immediate neighbourhood of such surfaces the combustion of the gases would cease altogether, because the attractive influence of the surfaces would entirely prevent their motion; farther off, their combustion would be partial, and only at a comparatively great distance the particles of gas would be free to continue unimpeded the motion required to maintain combustion. On the other hand, the surfaces themselves must suffer from the motion of the particles of gas producing the flame, for, however small these particles might be, they produce, while in such violent motion, an amount of energy which acting constantly would in time destroy the surfaces opposed to them, just as "continual dropping wears away stone." This circumstance fully accounted for the fact that the inner sides of furnaces, and the materials they contained were soon destroyed, not by heat, but by the mechanical, and perhaps also by the chemical, action of the flame. It would seem strange that the heating power of a large volume of flame should be so much interfered with by the contact of its outer parts only with the inner sides of a large furnace chamber, if there was not another cause besides imperfect combustion to reduce the heating effect of a flame which touched the surfaces to be heated. A flame when in a state of combustion radiated heat not only from its outer surface, but also from its interior by allowing the heat to radiate through its mass. In this manner every particle of flame sent its rays in all directions, but if the flame itself touched anywhere combustion ceased there, free carbon was liberated and produced smoke which enveloped that part and prevented the rays of heat of the other portions of the flame from reaching it.

[1] Lecture by Mr. Frederick Siemens at the Royal Institution, Friday, May 7.

The author had avoided for various reasons referring to the subject of dissociation until recently, although it had been brought forward by several writers, and used as an argument against his new system of furnace; as according to these writers it would appear to be impossible to produce such exceedingly high temperatures as he claimed to reach. He had long held the opinion that appearances of dissociation not being observable in furnaces heated by radiation, but occurring in furnaces in which the flame was allowed to come into contact with surfaces, must be due to the action on the flame of those surfaces at high temperature. He was led to this conclusion partly from his own observations, and partly from descriptions of dissociation observed by others, amongst whom was his brother, the late Sir William Siemens, who described a case of dissociation (see lecture delivered March 3, 1879, at the Royal United Service Institution, entitled "On the Production of Steel, and its Application to Military Purposes") which occurred in a regenerative gas furnace constructed according to their old views of combustion and heating. *The conclusion at which he had arrived was, that solid surfaces, besides obstructing active combustion, must also at high temperatures have a dissociating influence on the products of combustion.*

In order to obtain information on this subject he examined the laws and theory of dissociation, and endeavoured to bring the various results obtained by scientific authorities into agreement with one another, and with his own experience, but failed entirely in doing so. The temperatures of dissociation of carbonic acid and steam, the two principal gases forming the products of combustion when ordinary fuel was used, vary very much according to these observers, and the results he had obtained in practice were different from most of them. He hoped to prove that the temperature at which dissociation sets in is, in most cases, much higher than generally admitted; and that the authorities he was about to refer to had omitted in almost all the experiments they had made to take into proper consideration one element which was liable to alter materially the results obtained by them. *This element was the apparatus used for those experiments as regards its surface, form, and material.*

In considering the question of dissociation, he proposed to commence with Deville, who first discovered and called attention to the dissociation of gases at high temperatures. He made numerous experiments with various gases, and fixed certain temperatures at which he found that either complete or partial dissociation took place. Without going into details, he might mention that Deville required to use vessels and tubes of definite dimensions, material, and structure, in order to obtain the results stated. One experiment had to be made with a porous tube, another required the use of a vessel with rough interior surfaces, or containing some rough or smooth material. In this way Deville arrived at a great variety of results, and although he did not state that the rough surfaces, or porous tubes, or the solid material placed inside the vessels which he employed, had any particular influence on the temperature at which dissociation took place, yet it would appear that he could not obtain his results without having recourse to those means. Deville's results depended very much upon the various kinds of surfaces he used in his experiments, if they were not entirely brought about by them; these experiments, moreover, were of a very complicated nature, so he proposed to pass on to more modern authorities, whose experiments were of simpler character, and less open to objection.

The most important experiments which modified those of Deville were due to Bunsen. Bunsen observed the dissociation of steam and carbonic acid by employing small tubes filled with an explosive mixture of these gases, to which suitable pressure-gauges were attached. On igniting the gaseous mixture, explosion took place, and a high momentary pressure was produced within the tube; from the pressure developed, Bunsen calculated the temperature at which the explosion took place, and found that it varied with the mixtures employed. He records the circumstance that only about one-third of the combustible gases took part in the explosion, from which circumstance he concluded that the temperature attained was the limit at which combustion occurred. To prove this, Bunsen allowed the gases sufficient time to cool, after which a second explosion was produced, and even a third explosion when time was allowed for the gases to cool down again. Bunsen obtained much higher temperatures for his limits of dissociation than other physicists; these were for steam about 2400° C., and for carbonic acid about 3000° C. These temperatures were probably higher than

are reached in the arts, as materials used in furnace-building would not withstand such temperatures for any length of time; but still he must call attention to the circumstance that if the influence of the inner surfaces of the tubes on the combustion of the gases therein could be removed, the dissociation temperatures arrived at would be found still higher. He could not admit that Bunsen's explanation of the cause of the second and third explosions was quite satisfactory, as it was not the cooling of the gases alone which rendered the subsequent explosions possible, but also the thorough re-mixture of the gases by diffusion after each explosion. This he illustrated by means of diagrams which represented—

(1) A tube filled with an explosive gas mixture which was shown white.

(2) The same tube immediately after an explosion had taken place, with a white margin to indicate the unexploded mixture close to the sides, and deep red, towards the middle of the tube, the exploded gases. The white was shown as merging into deep red by degrees, because close up to the sides the surfaces prevented explosion or combustion altogether; nearer the middle partial combustion took place, whilst only in the middle of the tube the gases found sufficient space for complete combination.

(3) The same tube after the burnt and unburnt gases had mixed by means of diffusion, which was coloured light red.

(4) The same tube immediately after the second explosion, coloured light red at the sides, turning into deep red by degrees towards the middle.

(5) The same tube after diffusion has done its work a second time, coloured a deeper shade of red.

(6) The same tube after the third explosion, coloured nearly deep red throughout, but still a lighter shade on the sides.

In Bunsen's mode of determining dissociation at high temperatures we had only to deal with the obstruction which surfaces offer to combustion, leaving out their dissociating influence at high temperatures, which affected most of Deville's results. For that reason Bunsen arrived at much higher dissociation temperatures than Deville, and his mode of experimenting possessed the advantage that it might lead to a proper settlement of the question of temperatures at which dissociation would set in when taking place in a space unencumbered by surfaces.

By taking a narrow tube of about the same size as Bunsen used for his experiments, and a hollow sphere of the same capacity, in both of which Bunsen's experiment should be repeated, the real dissociation temperature, if no surfaces were present to influence the result, might be approximately calculated.

Bunsen's method of experimenting, according to his view of the matter, should form the foundation of further research to determine the dissociation temperatures of products of combustion. Even if means were found for eliminating the influence of surfaces, no known material at our disposal could withstand the very high temperature to which the vessels or tubes would be subjected if experiments were carried out according to Deville's method.

That the surfaces of highly heated vessels or tubes either produce, or tend to produce, dissociation, had been corroborated lately by two Russian experimentalists, Menschutkin and Kronowalow. These gentlemen found that dissociation of carbonic acid and other gases was much facilitated when the vessels used for the experiments were filled with material offering rough surfaces, such as asbestos or broken glass.

The lecturer's view of the theory of dissociation caused or influenced by surfaces might be given as follows. Increase of temperature producing expansion of gases would reduce the attractive tendency of the atoms towards one another, or, in other words, diminish their chemical affinity. In the same ratio as the temperature was increased the repelling tendency of the atoms must increase also, until at last decomposition, or what is called dissociation, took place. This being admitted, it would follow that the adhesive or condensing influence of surfaces on the atoms of the gas, which action would increase at high temperatures, would assist this decomposition by increasing the repelling tendency of the atoms.

Victor Meyer, who at first disputed the accuracy of the results obtained by the two Russian physicists, ultimately accepted them, thus confirming the results he had arrived at in practical work with furnaces. Thus the question might be considered nearly settled, the more so as Meyer was himself a great authority in questions of dissociation, having carried out many interesting experiments. Meyer, for instance, proved dissociation by dropping melted platinum into water, and found that oxygen and hydrogen were evolved from the steam produced. There could be no doubt on this point, but the question arose whether heat was the sole agent that brought about the dissociation of steam in this case. In the first place the dissociating influence of the highly heated surfaces of platinum on steam had to be taken into consideration, and, secondly, the chemical affinity which platinum had for oxygen, and still more for hydrogen. The same remarks applied to Meyer's experiment of passing steam or carbonic acid through heated platinum tubes, in which case he obtained only traces of dissociation, the temperature being much lower. Other experiments might be mentioned, but none led to a different conception of the question.

There is one other circumstance connected with dissociation, proved by experiment, which, however, required explanation. It was considered as a sure sign that dissociation was going on when a flame whose temperature was raised became longer; this it was said could only be accounted for by dissociation having commenced. He agreed with this conclusion, but the experiments by which it had been proved had been made, like others referred to, in narrow tubes or passages in which the dissociating action of the heated surfaces must come into play. It was not alone the heat to which the gases were raised that in these cases caused dissociation and increased the length of the flame, but also the influence of the heated surfaces in contact with the combustible gases, more especially if these gases contained hydrocarbons. The extension of the flame was also partly due to the obstruction which the surfaces offered to the recombustion of the dissociated gases through want of space. If the same flame were allowed free development in a space unencumbered by surfaces, as in the lecturer's radiation furnace, no such extension of its length would be observed; but, on the contrary, it would get shorter with increase of temperature. This action could be best observed in the regenerative gas-burner exhibited, whose flame became shorter the greater the intensity of the temperature, and therefore of the light, produced. On the other hand, flame might be extended almost to any length if conducted through narrow passages; this might be seen in regenerative furnaces, which would send the flame to the top of the chimney if the reversing valves were so arranged that the flame, instead of passing through the furnace chamber, was made to burn directly down into the regenerators. No proper combustion could then take place in the brick checkerwork of the regenerative chambers, and the flame would consequently continue to extend until cooled down below a red heat, being ultimately converted into dark smoke; thus in this case the extensive surfaces offered by regenerators would act both ways, by preventing combustion, and by assisting dissociation.

It would be understood that regenerative furnaces themselves offered special opportunities for making experiments, most questions, indeed, being best settled by the results obtained in actual work. If dissociation set in the consequences were seen in want of heat, reduced output, and in destruction of furnace and material. If the causes of dissociation were removed, a rise in temperature, increased output, longer furnace life, and saving of material ensued. Similar results might be obtained with other furnaces, but the beneficial action would not be so great as in the case of the regenerative furnace, because the intensity of heat obtainable in them was much lower.

After describing a new regenerative gas stove he had lately introduced, the lecturer referred to the better distribution of the radiated heat by its use; he found that a room warmed by means of a stove or open fire, such as described, was of a more uniform temperature than when warmed by an ordinary fire or by a gas and coke fire, such as his brother was engaged in introducing into this country shortly before his death.

This, in his opinion, was mainly due to the fact that a source of radiant heat of low intensity but of large surface, sending out its rays at various angles, heated an object in its vicinity very much more than was the case with a smaller source of radiant heat of greater intensity, whose rays struck the object from one direction only, notwithstanding that both sources radiated the same quantity of heat. This action was illustrated by means of two diagrams exhibited, which represented two rooms, the one heated by a small flame of high intensity, and the other by a large flame of low intensity, both radiating the same quantity of heat. In each room two objects, globes or spheres, were repre-

sented, the one close to, and the other at a distance from the source of heat. The object in the one room near to the source having the large heating surface was almost enveloped in rays, while that in the second received rays only in one direction, the former therefore being much more heated than the latter. This difference did not occur when the two globes at a distance from the two sources of heat were compared. The law that the rays of heat diminished in the inverse ratio of the square of the distance was only correct as regards small but intense sources of heat, whilst the decrease of radiant heat took place in a much higher proportion in the case of large sources of heat of low intensity. This clearly proved that for the purpose of warming rooms by means of radiation, it was important that the heat should be concentrated in an intensely hot focus, as was the case in nature, our earth being warmed in this way by the radiant action of the sun.

ON THE EFFECT OF HEAT IN CHANGING THE STRUCTURE OF CRYSTALS OF POTASSIUM CHLORATE

IT was observed some time ago by M. Mallard (*Bulletin de la Société Minéralogique*, 1882, p. 214) that certain crystals, such as boracite and potassium sulphate, have their crystallographic character profoundly modified by exposure to a high temperature, and that in the case of potassium sulphate a number of hemitrope plates are thus formed.

Now, potassium chlorate, while it does not belong to the same crystal-family as potassium sulphate, shows a still more inveterate tendency to produce twins (such as would assuredly drive a Malthus to despair). It was therefore an obvious inference that heat might produce a similar physical change in this substance, although I have not been able to find any account of the experiment having been tried. The decrepitation of crystals of potassium chlorate, when heated, has of course been noted; but the wreck of the crystal has been always rather inadequately explained as due to the vaporisation of included films of water.

A clear transparent crystal of potassium chlorate, from which the inevitable twin plate had been ground away so as to reduce it to a single crystal-film about 1 mm. in thickness, was placed between pieces of mica and laid on a thick iron plate. About 3 cm. from it was laid a small bit of potassium chlorate, and the heat of a Bunsen burner was applied below this latter, so as to obtain an indication when the temperature of the plate was approaching the fusing-point of the substance (359° C., according to Prof. Carnelley). The crystal-plate was carefully watched during the heating, but no decrepitation took place, and no visible alteration was observed, up to the point at which the small sentinel crystal immediately over the burner began to fuse. The lamp was now withdrawn, and when the temperature had sunk a few degrees a remarkable change spread quickly and quietly over the crystal-plate, causing it to reflect light almost as brilliantly as if a film of silver had been deposited on it. No further alteration occurred during the cooling; and the plate, after being ground and polished on both sides, was mounted with Canada balsam between glass plates for examination. Many crystals have been similarly treated with precisely similar results; and the temperature at which the change takes place has been determined to lie between 245° and 248°, by heating the plates upon a bath of melted tin in which a thermometer was immersed. With single crystal-plates no decrepitation has ever been observed, while with the ordinary twinned plates it always occurs more or less violently, each fragment showing the brilliant reflective power above noticed. Doubtless the decrepitation is due to the wrenching asunder of the hemitrope plates, caused by their unequal expansion by heat in different directions.

The following brief account will show the nature of the changes which the crystal has undergone:—

(1) Examined in common white light, the ordinary crystals of potassium chlorate reflect no more light, either superficially or internally, than a plate of glass, in whatever position they are viewed.

The altered crystals, when similarly examined, reflect little light at small angles of incidence, but at all angles greater than about 10° they reflect light with a brilliancy which shows that the reflection must be almost total. This reflective power does not seem to be materially greater at high angles of incidence. When the plate is turned round in its own plane, two positions are found, differing in azimuth by 180°, in which the crystal reflects no more light than an ordinary crystal under the same conditions. In these cases the plane of incidence coincides with the plane of crystallographic symmetry.

The reflected beam is slightly iridescent; and when the plate is held obliquely and examined with a magnifier, a striated faintly-coloured structure is observable, resembling that of watered silk or mother-of-pearl. The coloured bands always lie parallel to the plane of symmetry. When the reflected light is examined with a spectroscope, it is found to give a rather complicated spectrum containing numerous narrow absorption-bands. In some specimens these bands are fairly straight and regular, but in most cases they are rather wavy, and vary in thickness in different parts of their length, appearing somewhat like the interlacing twigs in a bundle of sticks. As the angle of incidence is increased, these bands move towards the more refrangible end of the spectrum, while others appear and join in the procession.

The spectrum of the transmitted light is, of course, strictly complementary to that of the reflected beam; and both of them strongly resemble the spectra given by some of the iridescent crystals described by Prof. Stokes (see NATURE, vol. xxxi. p. 565), and also by many sections of opal and mother-of-pearl, and by films of decomposed glass.

(2) When examined in a parallel beam of plane-polarised light, the ordinary crystals show little or no colour, unless held so that the light passes nearly in the direction of the optic axes, when the usual broad, rather faintly-coloured bands are seen. The altered crystals, on the contrary, give in all positions (except when the light passes through nearly normally, or when the plane of polarisation is either parallel or perpendicular to the plane of symmetry) a most complicated and brightly-coloured pattern, resembling that which is shown by many of the complicated macled crystals of amethystine quartz, which vary, like patterns on watered silk, with slight changes in the direction of incidence of the light.

(3) When examined in a micro-polariscope, in plane-polarised, highly convergent white light, the ordinary crystals show the usual isochromatic lemniscates surrounding the optic axes, which latter are themselves just visible at the edge of the field. In the altered crystals nothing of the kind is visible, only patches of colour distributed rather irregularly over the field, somewhat like those of certain of Nörremberg's mica-selenite combinations.

(4) When homogeneous (sodium) light was substituted for white light in the micro-polariscope (an expedient which is of great use in simplifying and giving definiteness to the phenomena shown by crystals), the remarkable nature of the structural change which heat had caused was much more clearly apparent. The ordinary crystals simply showed the usual multitude of curved isochromatic bands symmetrically arranged round the optic axes and filling the whole field. The altered crystals showed nothing of the kind; but a set of hyperbolas appeared—the form of the isochromatic curves of extremely high order which are given by biaxial crystals when the directions of the optic axes make a very large angle with the normal to the surface of the plate (see Verdet, *Œuvres*, vol. vi. pp. 172-175). These hyperbolas are not rectangular, thus proving that the optic axes do not lie in the plane of the plate (as in the case of cleavage plates of selenite); but they so nearly do this that I could not, even by immersing the plate in oil, satisfactorily determine their precise position. The bands are rather irregular and shifty, as is usual in composite macles; in some parts of a crystal they may appear as the central portions of a lemniscate-system.

(5) It seemed desirable to examine the effect of heat upon the crystal during its progress, so as to determine whether the change of structure takes place at the period of the formation of the reflective layer. For this purpose a polished plate of potassium chlorate was clasped in a copper holder (like that used for plates of selenite in Mitscherlich's well-known experiment), so that it could be placed in the field of the polariscope and examined while its temperature was gradually raised by the application of a lamp-flame to the outer extremity of the holder.

The ordinary set of isochromatic curves lasted nearly unchanged for some time as the temperature rose, but at a certain point they faded away like a dissolving view; and then out of the confusion there emerged the set of hyperbolas above mentioned, which grew in definiteness and regularity, but did not

otherwise alter until the field quickly became dark owing to the fusion of the crystal. This seems to indicate that the change in structure begins quite independently of the formation of the reflective layers, the latter being only an incident occurring at a particular stage of the cooling.

(6) It would seem that something of the following kind happens to the crystal. It is, of course, anisotropic in structure, and the effect of heat is to set up a molecular strain which at a certain point of temperature causes so strong a shearing action between nearly contiguous layers of the substance that whole rows of crystal elements lying between these layers are rolled over, as it were, by the "couple" applied to them, until they take up their "second positions of equilibrium," as M. Mallard would say (see his paper "Sur la Théorie des Macles," *Bull. Soc Min.*, December 1885, p. 467). If these latter positions were such as to bring the *obtuse* bisectrices (supplementary lines) into parallelism with a normal to the main plate, the occurrence of the hyperbolas above described would be fully accounted for. Such an action would be of the same general character as that which takes place in calc-spar when macles are being developed in it by Reusch's method; viz. by carefully compressing a crystal of it in a definite direction (*Pogg. Ann.*, vol. cxxxii. p. 445), I have succeeded by properly regulating the direction and amount of the pressure in making spar-macles containing numerous "planes of sliding" (*Gleitflächen*, as Prof. Reusch calls them), which reflect light with a pearly lustre, and almost as brightly as the potassium chlorate macles described above.

It has yet to be explained, however, why the intense reflective power does not show itself during the process of heating, when the tilting over of the crystals would certainly take place, and not until a particular stage of the cooling is reached. I am inclined to believe that this may be due to the substance acquiring a certain amount of plasticity at high temperatures, such as has been observed by M. Mallard in crystals of nitre under similar circumstances. This may prevent any loss of optical continuity until a certain critical point in the cooling has been reached; and at this point the displaced crystal elements suddenly part company with their unaltered neighbours, leaving a numerous series of parallel tubular cavities, precisely like those which are undoubtedly present in calc-spar macles formed by Reusch's method. The opposite sides of these parallelogrammatic cavities may be so near each other that the rays reflected from them may interfere, and give the colours of thin plates corresponding to a rather high order in Newton's scale. Although a large amount of light must escape reflection at any single cavity, yet if the transmitted rays encountered a large number of precisely similar and similarly situated cavities at slightly lower levels in the crystal, the sum of the partial reflections would produce an effect almost equivalent to a total reflection of the original incident ray, and a corresponding deficiency in the amount of light transmitted through the whole plate. The brilliancy of the colours in the light reflected from the well-known films of decomposed glass is accounted for in precisely the same way, and the successive separate films of glass can be easily seen under a microscope at the edges of the compound film, where they only partially overlap.

The fact that no brilliant reflection is observed in and near the plane of symmetry of the crystal may be due to the sides of the cavities in a given horizontal row not lying strictly in the same plane, but being slightly inclined alternately in opposite directions, so as to form a series of anticlinals and synclinals, or ridges and furrows like those of a roof. Thus a beam of light incident in the plane of symmetry would be reflected in directions lying a little to the right and left of this plane, and not in the plane itself. The satin-like appearance of the reflecting layers, already alluded to, would be fully accounted for by such a structure.

The changes above described seem of interest as bearing upon the cause of the strong iridescence of some crystals of potassium chlorate, about which I may have something to say in a future communication.

Eton College, May 10

SCIENCE IN RUSSIA

THE last volume of the *Memoirs* of the Kharkoff Society of Naturalists (vol. xviii.) contains several papers of interest. All who have had to deal with Acarides, and are acquainted with the difficulties of their classification, will welcome the elaborate memoir, by M. Krendowsky, on the Hydrachnids of Southern Russia. It is not a mere description of forms, with a more or less happy classification, but an elaborate contribution towards the systematic arrangement of this imperfectly-known subdivision. The embryogeny of the Hydrachnids, and especially their larval phase, have received special attention, no satisfactory classification being possible without that preliminary study. It appears also from M. Krendowsky's researches that many Hydrachnids of Southern Russia are really temporary parasites on several insects, mollusks, and sponges, especially when young and in the state of six-footed larvæ. The Hydrachnids of South-Western Russia belong to thirty-five species (nine species each of *Nesæa* and *Arrenurus*, five of *Atax*, and four of *Limnesia*); the author has been led to revise the whole of the classification of the freshwater Acarides, and gives it complete, with analyses of each family, as well as of the very numerous genera.

Another paper of great interest is devoted by the same author to the estuaries of the Bug, Dnieper, and the smaller ones in the neighbourhoods of Kherson and Odessa. This paper is full of the most useful information as to the characters and geological history both of these estuaries and the *limans*, which are now shut off from the sea by their sand-bars, and have become mere elongated salt lakes.

Prof. Lewakowsky contributes to the same volume a paper on the Jurassic limestones of the Crimea, based especially on their micro-structure. It appears that they mostly contain very small debris of corals and rhizopods; they are not coral structures, as was supposed, but have much likeness to what Dana describes as beachsand-rock. Like the clay-slates of the same formation in the Crimea, they have been deposited in a wide basin which extended into Kherson and Ekaterinoslav, and they were composed of materials brought from the south, from a continent which occupied part of what is now submerged by the Black Sea. M. Genjouriste's researches into the microscopical structure of the coal of the Donez Basin are interesting inasmuch as they show that the prevailing materials for the formation of this coal were the higher vascular Cryptogams, and not Algæ, as was sometimes supposed by Russian geologists. Dr. M. Dybowsky's additional note on the Spongilla *Dorvilia stepanovii*, one of the most interesting discovered in Europe, contains a description of the structure of its gemmulæ, with the porous and "cirrous appendages." The note, as also the preceding papers, are accompanied by several plates.

SCIENTIFIC SERIALS

The Quarterly Journal of Microscopical Science, vol. xxvi. part 3, April 1886, contains a memoir on the leeches of Japan, by Dr. C. O. Whitman (plates 17 to 21). A short abstract of this important memoir has been given in our Biological Notes.—Contributions to the embryology of the Nemertea, by Prof. A. A. W. Hubrecht (plate 22). No. 1 is an account of the development of *Lineus obscurus*, Barr. These investigations, already published in the Dutch language, are fully detailed in this paper, and the plate gives the details of the principal results, combined into fifteen diagrammatic tracings. In one section the earliest developmental stages and the derivatives of the primary epiblast; in a second the hypoblast before the shedding of the primary larval integuments; and in a third the mesoblast, are treated of.—On the early development of *Julus terrestris*, by F. G. Heathcote, M.A. (plates 23 and 24). This is the first part of an essay on a subject not treated of by British naturalists since the days of Newport. It treats of the segmentation of the ovum, which shows a remarkable resemblance to that found in Amphipods by Uljanin. The formation of the blastoderm is such as is generally found in tracheate development. The cells, which at the conclusion of the blastoderm formation remain within the yolk, represent the endoderm. The mode of formation of the mesoderm almost exactly resembles that described by Balfour for spiders. In a future paper the author intends describing the further developmental stages of the embryo.—William A. Haswell, M.A., on the structure of the so called glandular ventricle (*Drüsenmagen*) of Syllis (plate 25). This organ is in reality a well-developed muscular gizzard, and contains no glands in its walls. The muscular elements of the organ present an embryonic character containing as they do a polynucleated core.—Arthur B. Lee, on Carnoy's cell researches (plate 26). While Carnoy's conceptions of the cell body do not materially differ from received views, the author of this paper thinks that sufficient attention has not been given to his labours on the

question.—Prof. E. Ray Lankester, the Pleomorphism of the Schizophyta. A reminder of the simple fact that ten years ago Prof. Lankester called attention to the pleomorphism of the Schizophyta in a paper in this *Journal*, which attracted the deep attention of all those botanists who had taken any interest in the subject.

Journal of Anatomy and Physiology, April 1886, vol. xx., part 3, contains :—Dr. J. W. Frazer, on the action of infused beverages on peptic digestion. This paper is a continuation of one in the eighteenth volume of this *Journal*, and is based on the results of the same experiments, the difference being that the amount of peptones dialysed, instead of being estimated as the total organic matter, as was done in that paper, are here estimated by the amount of organic nitrogen.—W. A. Lane, some variations in the human skeleton ; asymmetry of skull, spinal column, &c., bifid ribs.—Dr. R. L. MacDonnell, case of bicipital rib.—Dr. R. W. Shufeldt, osteology of *Conurus carolinensis* (plates 10 and 11). The extermination of this parrot appears imminent. To this memoir there is appended a synopsis of the skeletal characters of this bird which exhibit many points of interest.—On a Navajo skull (plate 12), with a note by Sir Wm. Turner.—J. Bland Sutton, on the origin of certain cysts (plate 13).—Dr. J. Lockhart Gibson, the blood-forming organs and blood-formation : an experimental research (plate 14) (continued). Among the chief conclusions are the following: throughout life, nucleated red cells, derived from white corpuscles and colourless marrow-cells, are the only predecessors of the non-nucleated red blood-corpuscles. The transformation takes place in the bone marrow, spleen, and lymphatic glands ; the red bone marrow in extra-uterine life plays the more important part in the work, the spleen a subordinate one ; the lymphatics, while chiefly producing white, do also produce red corpuscles. Both colourless cells and nucleated red cells multiply by division in the blood-forming organs, and in these latter there are also to be found cells whose function appears to be to break down red blood-corpuscles.—Dr. E. E. Maddox, on the relation between convergence and accommodation of the eyes.—Dr. R. Robertson, a contribution to splenic pathology (plate 15).—Dr. F. Tuckerman, supernumerary leg in a male frog (*Rana palustris*) (plate 16).—Dr. D. Noël-Paton, the nature of the relationship between urea formation and bile secretion. Both these phenomena would seem to depend in large measure on the destruction of blood-corpuscles, and through this they necessarily bear a direct relationship to one another.—Prof. D'Arcy W. Thompson, on the hind limb in *Ichthyosaurus platyodon*, and on the morphology of vertebrate limbs.—Sir Wm. Turner, on the lumbar curve of the spinal column in several races of men (see also abstract of a memoir on this subject by Prof. D. J. Cuningham, NATURE, vol. xxxiii. p. 378).—Anatomical notes.

American Journal of Science, April.—On Lower Silurian fossils from a limestone of the original Taconic of Prof. Emmons, by James D. Dana. These fossils were recently found in the "sparry" or western limestone of the Taconic system, that is, the oldest limestone stratum of the system according to Emmons. They come from Canaan, New York, near the Massachusetts border, and several species have been determined by Prof. Dwight, notwithstanding the metamorphism of the rock. They include remains of Murchisonias, Pleurotomarias, Crinoids, Fenestellæ, a Trilobite, and probably some Brachiopods, showing that this limestone is not pre-Cambrian or Cambrian, but belongs probably to the Trenton or Lower Silurian age of the Eastern or Stockbridge limestone.—Preliminary report of S. W. Ford and W. B. Dwight upon the fossils obtained in 1885 from metamorphic limestones of the Taconic series of Prof. Emmons at Canaan, New York : A. Explanatory statement with reference to the palæontological investigations at Canaan, by W. B. Dwight. The authors are strongly inclined to the opinion that the limestones of Canaan, which have yielded these fossils, are of Trenton age.—On surface transmission of electrical discharges, by H. S. Carhart. A practical bearing of the experiments here described and illustrated is that there is no sufficient scientific basis for making lightning conductors of large surface, and that large sectional area is essential to ample conductivity.—The minerals of Litchfield, Maine, by F. W. Clarke. The paper contains a careful study and analysis of the elæolite, cancrinite, sodalite, hydronephelite (new species), albite, and lepidomelane from the numerous boulders of an elæolite rock scattered over the district between Litchfield and West Gardiner, in Kennebec County, Maine.—On the chemical behaviour of iron in the magnetic field, by Edward L. Nichols. A set of experiments with aqua-regia, nitric acid, hydrochloric acid, and sulphuric acid is described in illustration of the phenomenon that, when finely-divided iron is placed in a magnetic field of considerable intensity and exposed to the action of an acid, the chemical reaction differs in many respects from that which occurs under ordinary circumstances. The experiments are preliminary to a more complete investigation of the novel series of effects developed by them.—The inculcation of scientific method by example, with an illustration drawn from the Quaternary geology of Utah, by G. K. Gilbert. This paper is a reprint of the Presidential Address read before the American Society of Naturalists at Boston, December 27, 1885. It discusses, not the results nor the subject-matter of the several sciences with which naturalists are concerned, but their methods of investigation and their methods of teaching generally.—Nova Andromedæ, by Asaph Hall. The history of the discovery of the new star in Andromeda by Dr. Hartwig, of Dorpat, last August, its observation and gradual fading away, forms the subject of this paper.—On some new forms of the Dinocerata, by W. B. Scott. What appears to be a missing link between the two sub-orders of Amblypoda (the Coryphodons of the Wahsatch Eocene and the Dinocerata of the Bridger) is here described under the name of Elachoceras. It was discovered by the Princeton Expedition of 1885 in the Bridger beds of Henry's Fork, Wyoming, and represents a genus allied to Uintatherium, without upper incisors, and having six molars of the Uintatherium type and large upper canine tusks, but without nasal protuberances, and having only rudiments of the maxillary and parietal protuberances. The supra-occipital is pierced by two large venous foramina placed one on each side of the median line. In the same locality, but at a somewhat higher level, was found a large Uintatherium skull, undoubtedly representing a new species (*U. alticeps*) of that genus.

The American Naturalist for April 1886 contains :—On the ancestry of Nasua, by Saml. Lockwood.—On the mechanism of soaring (illustrated), by J. Lancaster.—The Stone Age in Vermont (illustrated), by Geo. H. Perkins.—On Grosse's classification and structure of the Mallophaga (illustrated), by Geo. Macloskie.—On traces of a cyclone which passed over Western Indiana more than 300 years ago, by Jno. T. Campbell.—On the mounting of fossils (illustrated), by F. C. Hill.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 1.—"On a New Form of Stereoscope." By A. Stroh.

Two optical lanterns are placed side by side, as for dissolving views. Two transparencies, photographed in the same manner as if intended for an ordinary stereoscope, are placed one in each lantern, and projected on a screen in such a position that they overlap each other as nearly as possible. The picture which is intended to be seen by the right eye may be placed in the right-hand lantern, and the other in the left.

Supported by suitable framework, and in front of the two lenses of the lanterns, is a revolving disk, portions of which are cut away, so that during its revolutions it obscures the light of each lantern alternately, or, in other words, so that only one picture at a time is thrown on the screen. A continuous change from one picture to the other is thus obtained.

In the same framework, and in convenient positions for the observers, two pairs of eye-holes are provided, one pair on either side of the apparatus. Behind each pair is also a rotating disk, and these disks are connected by suitable wheel-work or driving-bands with the one previously mentioned, in such a way that the three disks rotate together, and at the same rate. The two last-named disks are also so cut that they will obstruct the view through the right and left eye-holes alternately.

Finally, the connection between the three disks has to be so arranged that the time of obscuring the view through the right eye-holes, or the left eye-holes, shall coincide with the time when the light is shut off from the right or left lens of the lanterns respectively.

It is obvious that by this arrangement an observer can only see the picture projected from the left lantern with the left eye, and the one from the right-hand lantern with the right eye.

The rotation of the disks must be of such a rate that the alternate flashes of the right and left pictures on the corresponding

eyes follow in such rapid succession that the impression made by one flash does not diminish sensibly before the next flash on the same eye is received. The number of flashes for each eye which is required to produce an apparently continuous view, without any flickering effect, is from thirty to forty per second. As the disks are so cut as to produce two flashes for the right eyes and two for the left in one revolution, they must consequently be kept rotating at a rate of from fifteen to twenty revolutions per second.

The rotation of the disks is effected by a driving-wheel and band worked by a crank handle at the back of the apparatus.

The perspective effect obtained by the above arrangement is very perfect, the image of each object standing out in solid relief.

Considering that by this arrangement the two eyes never see at the same time, and that each eye views its picture after the other, it is interesting to find that the persistence of vision so completely bridges over the alternate interruptions to which it is subjected as to produce the effect of a continuous view.

The advantages claimed for this form of stereoscope are: that the pictures can be enlarged to such an extent as to appear equal to or even larger than the original objects from which they were taken; and that the eyes in looking at the pictures are not in any way subjected to strain by lenses, prisms, or reflectors, or by the difficulty which some persons experience in getting the two pictures to superpose. For each eye views its corresponding picture in exactly the same position it would see it in if it were looking at the original, since the two pictures are practically in the same place, which is not the case in any other form of stereoscope.

Although with the apparatus as here described only two persons can see the pictures at the same time, it would not be very difficult to construct it so as to be available for a greater number. The side disks above described only serve to control one pair of eye-holes each, but by making them larger they would serve for two pairs each, thus accommodating four observers. By increasing the number of disks, the number of observers might be increased proportionately.

May 6.—"The Influence of Stress and Strain on the Physical Properties of Matter. Part I. Elasticity (continued). The Effect of Change of Temperature on the Internal Friction and Torsional Elasticity of Metals." By Herbert Tomlinson, B.A. Communicated by Prof. W. Grylls Adams, M.A., F.R.S.

The author has recently had the honour of presenting to the Society a memoir relating to the internal friction of metals when vibrating torsionally at temperatures ranging from 0° C. to 5° C. He now brings forward results which have been obtained in experiments on the effect of change of temperature on the torsional elasticity and internal friction of metals. The apparatus used and the mode of experimenting are fully described in the paper, so that it will be sufficient, perhaps, to state here that the vibration-period and the logarithmic decrement were very carefully determined at four different temperatures between 0° C. and 100° C., and that the formulæ were worked out by the method of least squares. These formulæ were given in tables.

From a consideration of the tables it may be gathered that:—

(*d*) The torsional elasticity of all metals is temporarily decreased by rise of temperature between the limits of 0° C. and 100° C., the amount of decrease per degree rise of temperature increasing with the temperature. To this may be added that the percentage decrease of torsional elasticity produced by a given rise of temperature is for most metals about twenty times the corresponding percentage increase of length.

(*e*) If we start with a sufficiently low temperature the internal friction of all annealed metals is first temporarily decreased by rise of temperature and afterwards increased. The temperature of minimum internal friction is for most annealed metals between 0° C. and 100° C.; for most hard drawn wire, however, the temperature of minimum internal friction is below 0° C.

(*f*) The temporary change, whether of the nature of increase or decrease, wrought by alteration of temperature in the internal friction of metals, is in most cases enormously greater than the corresponding change in the torsional elasticity.

Linnean Society, May 6.—Sir John Lubbock, Bart., President, in the chair.—Prof. H. Marshall Ward was elected a Fellow of the Society.—Mr. D. Morris exhibited a number of living beetles (*Pyrophorus noctilucus*) from the island of Dominica. These had been fed on sugar-cane during the voyage to England. On the meeting-room being darkened, the phosphorescent show of light emitted by the insects was very brilliant.—Dr. Chas. Cogswell drew attention to framed water-colour drawings of *Lettsomia aggregata* and *Fothergilla gardeni*, botanical mementos of the two distinguished physicians Lettsom and Fothergill.—Sir J. Lubbock's paper on forms of seedlings was, by request, adjourned, so as to give opportunity for discussion of Mr. Romanes's communication.—Mr. G. J. Romanes then read his paper on physiological selection: an additional suggestion on the origin of species. A full account of this paper will appear in a future number.—Thereafter the two following papers were read in abstract:—Descriptions of new species of Galerucidæ, by Joseph S. Baly.—On some new species of the genus *Metzgeria*, by Wm. Mitten.

Geological Society, April 21.—Prof. J. W. Judd, F.R.S., President, in the chair.—Henry Fisher, Frederick Edwin Harman, Henry Johnson, Edward Alloway Pankhurst, and Henry Woolcock were elected Fellows of the Society.—The following communications were read:—On a certain fossiliferous pebble-band in the "Olive group" of the eastern Salt Range, Punjab, by A. B. Wynne, F.G.S. The principal object of this paper was to oppose the views recently published by Dr. Waagen as to the age of certain Boulder-beds in the Salt Range of the Punjab. By that author these beds had been considered contemporaneous with each other, and assigned to the epoch of the Coal-measures, in consequence of the discovery by Dr H. Warth of Carboniferous fossils, especially Australian forms of Conularia, in nodules restricted to a particular layer in the upper part of a Boulder-bed in the eastern Salt Range. Mr. Wynne adduced evidence to show that the fossils in question occur, not in concretions, as supposed by Dr. Waagen, but in pebbles evidently derived from an older series; and consequently there was no proof that the Boulder-bed in question was older than the Cretaceous Olive-beds with which it had hitherto been associated. The principal Boulder-beds in the Salt Range were then briefly noticed; those beneath the Carboniferous Limestone west of the Indus, those near Amb and Sakesir peak, associated with the "purple sandstone," "Obolus-beds," and "speckled sandstone," and those in the eastern portion of the Salt Range, amongst the beds of the "Salt pseudomorph zone" and "Olive group" being successively passed in review, and their relations to overlying and underlying strata explained. It was shown that Boulder-beds and conglomerates containing pebbles and boulders of the same crystalline rocks are not confined to one horizon. In conclusion, the resemblance of the rock, of which the pebbles containing Conulariæ, &c., were formed, to that forming some of the "magnesian sandstone" and "Obolus-beds" was pointed out, and it was suggested that the pebbles in question may have been derived from representatives of those beds formerly existing to the southward.—On the phosphatic beds in the neighbourhood of Mons, by M. F. L. Cornet, For.Corr.G.S. These beds are situate in the province of Hainaut, near the town of Mons (Belgium); the workings have increased of late years, and in 1884 yielded 85,000 tons of phosphate. They occur in the Upper Cretaceous, which is exceptionally well developed in the district, filling a trough in the Carboniferous rocks, and itself denuded for the reception of Tertiary and Quaternary beds. Omitting all Cretaceous groups below the middle of the fifth stage, the following is the sequence of the Cretaceous beds which contain the phosphatic series:—C. Tufaceous chalk of Ciply, with the Poudingue de la Malogne at its base. D. *Brown phosphatic chalk of Ciply*. E. Coarse chalk of Spiennes. F. White chalk of Nouvelles. F is a pure white chalk with some flints, and contains *Belemnitella mucronata*, *Rhynchonella octoplicata*, *Terebratula carnea*, *Ananchytes ovatus*, &c.,—an horizon well known throughout North-Western Europe. Series E and D represent one geological horizon characterised by Ostreæ, Brachiopoda, &c., in great numbers, but also containing *Belemnitella mucronata*, and lying between two distinct planes of erosion. The brown phosphatic chalk (D), which forms the upper division of the series, is about 70 feet thick, and may be described as consisting of three parts; the upper is tolerably pure carbonate of lime, but in its lower portion becomes charged with brown granules mainly consisting of phosphate of lime; these continue to increase towards the central or main phosphatic mass, which is also highly fossiliferous in places. This central portion constitutes the main phosphatic beds, but the amount of phosphoric acid (dry) is not more than 12 per cent. Hence, it is necessary to increase the richness in phosphate of the deposit in order that it may be available for

conversion into a superphosphate. This may be done by mechanical means. But nature has already partially anticipated this process, and the result has been a deposit known as "rich phosphate," containing about 25 per cent. of phosphoric acid. This occurs in wide cracks and holes in the ordinary phosphatic chalk. It usually occurs as a fine sand-like powder, and is evidently the result of the action of carbonated waters upon the phosphatic chalk, whereby the amount of carbonate of lime is reduced. This is especially the case where the phosphatic chalk is not protected by the tufaceous chalk of Ciply, but is only covered by Tertiary or Quaternary beds. The author calculates that each square foot of the phosphatic basin, which he estimates approximately at 5 miles by 3, contains 355 lbs. of tribasic phosphate of lime. Finally, he intimates how the phosphatisation of the chalk may have been brought about.

Physical Society, May 8.—Prof. H. McLeod, F.R.S., Vice-President, in the chair.—Mr. W. A. Price was elected a member of the Society.—The following communications were read:—On a modified form of Wheatstone's rheostat, by Mr. Shelford Bidwell. A wire is coiled upon a non-conducting cylinder as in the ordinary forms of rheostat, one end of the wire being in contact with the brass axle of the cylinder. A screw is cut upon the axle, the pitch being equal to the distance between the consecutive turns of the wire, and this, working in a fixed nut, causes the whole cylinder to travel in the direction of its axis. A fixed spring bears upon the wire at a convenient point, and by the travelling motion of the cylinder this point of contact remains fixed in space, and the effect of turning the cylinder is to introduce more or less resistance between the spring and the brass axle. Binding screws on the base of the instrument are in contact with the nut and the bearing spring. Though this arrangement has several obvious advantages over the usual forms, Mr. Bidwell does not recommend it in cases where it is required to introduce a known resistance, but where it is important to adjust a resistance to a nicety, or to cause a continuous variation, it is of great use.—Prof. Perry, remarking upon the importance of being able to vary a resistance gradually, described an instrument he had used with advantage. A number of plates of gas-carbon are placed between two parallel copper plates, one of which is fixed and the other adjustable by a screw; by applying pressure by means of the screw the resistance between the plates can be varied uniformly and regularly from 2 to 10 ohms, beyond which point the increase is very rapid.—On a theorem relating to curved diffraction-gratings, by Mr. Walter Baily. In a paper read before the Society in January 1883 the author showed that if a plane be taken perpendicular to the lines of a curved diffraction-grating, and a normal to the grating be taken as the initial line, the equation—

$$\frac{\cos^2\theta}{r} = \frac{\cos\theta}{c} + \frac{1}{d}$$

(in which c is the radius of curvature of the grating, and d is an arbitrary constant), gives a curve having the property that if a point of light be placed anywhere upon it the curve is the locus of the foci of all diffracted rays whether reflected or transmitted. In the present investigation d is supposed to be greater than c, which allows of the source of light being at infinity. The points where the curve given by the above equation cuts the normal are called the normal foci. There are two of these, one relating to the reflected and the other to the transmitted light, the grating being supposed to consist of a number of opaque lines in space. It is then shown that if the grating be supposed to turn about the line in it intersecting the initial line, the normal foci will trace out two parabolas whose common focus is the origin, and common latus rectum is equal to the diameter of curvature of the grating, the parabola for reflected light being convex to the source of light, and that for transmitted light concave.—On some thermodynamical relations, part iv., by Prof. W. Ramsay and Dr. Sydney Young. The first part of this communication deals with Profs. Ayrton and Perry's criticisms upon the previous papers by the authors upon this subject. In the second part a brief review is given of the various attempts that have been made to represent the pressure of a saturated vapour as a function of the temperature.

Anthropological Institute, May 11.—Mr. Francis Galton, F.R.S., President, in the chair.—Mr. Galton read some notes on permanent colour-types in mosaic, in which he advocated the adoption of certain specimens of mosaic material as permanent specimens of standard colours for the description of tints of skin. The original paintings by Broca, as well as the lithographs from them, have already changed colour, and some more permanent standard is greatly needed. There can be no question as to the persistence of the colours of mosaic: some specimens in St. Peter's at Rome, that are more than a century old, have the appearance of being brand-new. The material is inexpensive, and as the variety of tints in the Vatican manufactory is very large, the flesh tints appropriate to European nations alone being about 500 in number, there would be no difficulty in selecting such a series as anthropologists desire.—Prof. Flower exhibited a Nicobarese skull, sent over by Mr. E. H. Man, together with some photographs of the natives.—Prof. Thane read a paper by Prof. A. Macalister on some African skulls and on a New Ireland skull in the Anatomical Museum of the University of Cambridge.—Dr. Garson reported that the correspondence as to an international agreement on the cephalic index had been brought to a satisfactory conclusion, and that the scheme advocated by him in his paper read before the Institute in February last had been accepted by sixty of the leading anthropologists on the Continent.—Dr. Garson read a paper on the skeleton and cephalic index of Japanese.

Entomological Society, May 5.—Prof. J. O. Westwood, M.A., in the chair.—The following were elected Fellows:—The Rev. E. N. Bloomfield, M.A., Mr. F. Fitch, Mr. A. J. Rose, and Mr. W. E. Nicholson.—Mr. J. Jenner-Weir exhibited a large spiny Lepidopterous larva from Western Africa.—Mr. Stevens exhibited *Apion sorbi* and other Coleoptera recently obtained in the Isle of Wight.—Mr. Crowley exhibited four specimens of *Leto venus*, a large moth belonging to the family *Hepialidæ*, from Natal.—Mr. Howard Vaughan exhibited a long series of *Cidaria immanata* from Kent, Surrey, Perthshire, Isle of Man, Isle of Arran, the Orkneys and Shetlands. He also exhibited *C. russata* from various localities in the south of England, and from Perthshire, Argyllshire, and the Islands of Arran, Lewis, and Hoy. Mr. Vaughan further exhibited varieties of *C. suffumata* from Dover and Darlington. Prof. Westwood commented on the interesting nature of the exhibition of *C. immanata*, and stated that he had never before seen such a wonderful collection of varieties of a single species.—The Rev. W. W. Fowler exhibited *Staphylinus latebricola* and *Quedius truncicola*, both from the New Forest.—The Secretary exhibited, for M. H. de la Cuisine, of Dijon, coloured drawings, life-size, of a variety of *Urania crœsus* and a variety of *Papilio memnon*.—Mr. G. Elisha exhibited specimens of *Antispila pfeifferella*, together with the cases, and the leaves mined by the larvæ.—Mr. J. W. Slater read a paper "On the Origin of Colours in Insects," in which he showed that the assertions of Mr. Grant Allen, that all brightly-coloured insects were flower-haunting species were incorrect, and that many brilliantly-coloured insects were carnivorous. Mr. McLachlan said that the physiological question in connection with colour had not been paid attention to; he thought that colour in insects was, to a great extent, dependent upon the circulation of fluids in their wings. The discussion was continued by Prof. Westwood, Mr. H. Goss, the Rev. W. W. Fowler, Mr. Jacoby, and Mr. Weir.

Victoria (Philosophical) Institute, May 3.—A paper by M. Maspero, describing his discovery of many Syrian geographical names in the lists of Thothmes III., was read. It was illustrated by a map, specially prepared by the author, as an aid to the inquirer in following his description of the Egyptian account of the events connected with each name. M. Maspero concluded his statements in the following words:—"Such are the observations which a long study of the lists has suggested to me. I have elsewhere given the justification of my transcriptions. I have endeavoured to bring to my identifications the same prudence that I have exercised in my transcriptions. The The names enumerated arrange themselves almost wholly in the districts that surround Megiddo; Qodshu, Damascus, and two or three other towns at most belong to countries comparatively remote. This result, to which the independent study of the lists has led me, arises clearly from the history of the campaign as the inscription at Karnak makes it known to us. In the year 23 (of his reign) Thothmes III. set out from Gaza, cleared Carmel, beat the confederates, including the prince of Qodshu, under the walls of Megiddo, besieged and took the town, then returned to Egypt without pushing farther on towards the north. The fall of Megiddo was decisive, for, as Thothmes III. has himself observed, 'every chief of the whole country [was shut up] in it, so that the capture of Megiddo was as good as the

taking of a thousand towns.' When the war was finished he 'reinstalled the chiefs in their dignity' on condition that they should pay tribute. The stress of the campaign fell thus on the plain of Esdraëlon: the Egyptian troops had long remained there, and had pillaged all the district round, not without pushing on to some distant points. On his return, when Thothmes III. built the pylon of Karnak with the booty of this campaign, he inscribed on the wall the names of the towns that he had sacked and which had unwillingly contributed to the completion of the edifice. The wall was large, and must be entirely covered. They took indiscriminately all the names of Galilee and Southern Syria that they knew, without troubling about the importance of the town itself: one name did as well as another for that matter." Sir C. Wilson, K.C.M.G., Mr. Boscawen, and others took part in the discussion.

Edinburgh

Royal Society, April 19.—Sir W. Thomson, Hon. Vice-President, in the chair.—Sir W. Thomson exhibited and described a new form of portable spring balance for the measurement of terrestrial gravity. In this instrument a metallic spring is used. The curvature of the spring when unweighted is such that, when one end is firmly clamped and a suitable weight attached to the other end, the spring becomes straight. When so arranged, the equilibrium of the spring and weight can be made as nearly unstable as is wished by simply tilting the instrument. Hence the apparatus can be made as delicate as necessary.—Mr. A. P. Laurie read a paper on the measurements of the E.M.F. of a constant voltaic cell with moving plates. Mr. Laurie determined the E.M.F. of a cadmium-iodine cell by drawing a large current from it, while the plates were kept moving. The value so got agreed with that given on open circuit as determined by the electrometer, thus showing that the fall of the current when the plates were not moving was due to alteration of the composition of the layers of liquid next the plate.—Mr. W. E. Hoyle read a note on the formation of Hectocotylus in Rossia.—Prof. Tait submitted a paper on some definite integrals.—Messrs. H. Rainy and R. D. Clarkson described the alterations in the electric conducting power of alloys at their melting-point.—The Rev. T. P. Kirkman submitted a communication on the reading of the circle, or circles, of a knot.

May 3.—Robert Gray, Vice-President, in the chair.—Dr. R. W. Felkin read notes on the Waganda, a Central African tribe.—J. Murray discussed the drainage-areas of continents, and their relation to oceanic deposits.—Dr. A. B. Griffiths read a paper on the vitality of the spores of parasitic fungi, and the antiseptic properties of ferrous sulphate.—Dr. R. Stockman discussed the action of benzoyl-ecgonin.

Paris

Academy of Sciences, May 10.—M. Jurien de la Gravière, President, in the chair.—On the formation of oxalic acid in plants (continued): *Amaranthus caudatus*, *Chenopodium Quinoa*, *Mesembryanthemum crystallinum*, by MM. Berthelot and André. Tables are given of the varying quantity of oxalic acid in the roots, stems, leaves, and flowers of these plants at different seasons of the year. The results throw great light on the essentially different physiological conditions of life and organisation in these various types of vegetation.—Observations of the comet 1886 *b* (Brooks II.), and of the new planet 258 (Luther), made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan. The new planet 258 was discovered by Dr. R. Luther at Düsseldorf on May 4 at 10 o'clock mean Düsseldorf time, when it occupied the position: 14h. 20m. R.A.; 9° 31′ Decl. When observed in Paris on May 7 it had the appearance of a planet of the twelfth magnitude.—Observations of the Brooks comets (1886) made at the Lyons Observatory, 6-inch Brunner equatorial, by M. Gonnessiat. Brooks I. appears like a diffused nebulosity with diameter of about 2′, and but slight central condensation. On May 4 the head of No. II. was bright narrow, and elongated in the angle of position 258°; tail visible for a space of about 12′, faint, and at its extremity spreading out towards the south.—Transformation of the horary angles and declinations to azimuths and heights, by M. Vinot. To supplement Warnstorff's tables, giving this transformation for the latitude of the Altona Observatory, the author has prepared others calculated for the latitude of Paris. They are presented to the Academy in the hope that, if preserved, they may enable other observers to dispense with long and tedious calculations.—On the employment of crusher manometers for the measurement of the pressures developed by explosive substances, by MM. Sarrau and Vieille. Two cases are recorded, in which the maximum pressure is accurately determined by the measured value of the crushing force.—Remarks on M. Ledieu's communication regarding marine engines, by M. Aug. Taurines. Attention is drawn to some errors in this communication presented on March 23, 1885, where M. Ledieu describes the dynamometric experiments made on board the corvette *Le Primauguet*, which he mistook for a simple aviso.—Note on certain sounds produced in vibrating metal plates by the discharges of static electricity, by M. E. Semmola. The conditions are described under which these sounds occur, but no theory is offered in explanation of the phenomenon.—Secondary electrolysis, by M. E. Semmola.—The island of Ferdinandea. the blue sun, and red after-glows of 1831, by M. A. Riccò, With a view to the elucidation of the crepuscular lights of 1883–84, the author gives a detailed account of the analogous phenomena which accompanied the appearance of the island of Ferdinandea in the Sicilian waters in the year 1831. It is pointed out that the atmospheric effects attending the eruption of Ferdinandea closely resembled those following that of Krakatão. But the ashes took no part in the production of the blue sun and red after-glows of 1831; consequently, the ashes of Krakatão would also seem to have had nothing to do with the similar light effects of 1883–84.—Note on the extraordinary halos seen at the Observatory of Parc Saint-Maur on March 29, 1884, and, with still more interesting light effects, on May 3, 1886, by M. E. Renou.—On products of decomposition of hypophosphoric acid: secondary hydrate, by M. A. Joly.—On the definite compounds of hydrochloric acid with the chloride of zinc, by M. R. Engel. The experiments here described have confirmed the theoretical view already advanced by the author, regarding the probable existence of one or more hydrochlorates of the chloride of zinc stable at the ordinary temperature.—On the combinations of quinone with the benzenic phenols, by MM. Ph. de Clermond and P. Chautard.—Action of the perchloride of phosphorus on the hydrocarburets, by MM. Alb. Colson and H. Gautier. It is shown that by means of the perchloride of phosphorus it is possible to substitute chlorine for hydrogen in the aromatic carburets. It thus becomes possible to prepare the symmetrical chlorurretted compounds in the fatty and aromatic series to the exclusion of the isomerous substances, which always accompany them in all other methods of preparation.—On the rancid element in butter, by M. E. Duclaux.—Note on sozolic acid (orthoxyphenylsulphurous acid), by M. Serrant. This acid, whose formula is $C_6H_4OH_{(1)}SO_2OH_{(2)}$, is described as even a more powerful antiseptic than salicylic and phenic acid. Being perfectly soluble, it may be taken inwardly without any inconvenience, and is rapidly and completely eliminated from the system.—On the position in the crab of the parasite *Sacculina carcini*, by M. A. Giard.

Berlin

Physiological Society, April 9.—Dr. Goldscheider spoke on the effect of menthol on the nerves of temperature. It was known that menthol (which for headaches has been extensively applied) generated a keen feeling of cold on being spread over the forehead. It was assumed that this feeling of cold resulted from the cooling of the skin consequent on evaporation. On the other hand, it was explained that the feeling of cold in the mouth produced by mouth washes containing mentha was due to an astringent effect of the mentha. The speaker had come to the conclusion that the two explanations referred to in the respective cases were neither of them correct. He made his experiments with a solution of menthol in lanoline, which was rubbed into circumscribed places of the skin. Measured with the thermometer, the places of the skin in question showed after the rubbing an increase of temperature of about 20° C., and yet for all that there was a quite decided feeling of cold. This feeling of cold was also observed when the place where the solution was rubbed in was protected against evaporation by a watch-glass. The feeling in question could proceed therefore only from a direct stimulation of the nerves of cold sensation. If of two places on the forehead exactly corresponding to one another, the one were rubbed with menthol salve and the other not, then bodies which before had produced no impression, as being indifferent, would now be felt as cold by the part of the skin where the rubbing was made, whereas there would be no perceptible impression at the other part. From these and several other experiments the speaker

concluded that the menthol exercised a specific influence on the nerves of cold, which were distributed with especial copiousness on the forehead. Menthol produced an effect on the nerves of warmth and the nerves of feeling of less amount than on the nerves of cold. A sensation of warmth after the rubbing in of menthol was obtained only at spots which were very rich in nerves of warmth. This was most easily obtained on the volar side of the lower part of the arm in the neighbourhood of the elbow joint. As analogous to his menthol experiments, the speaker called to mind how Prof. Herzen had quite recently communicated the observation that moderate pressure on the nerve-trunk produced a different effect on the cold feeling nerve-ends than on the warm feeling nerve-ends.—Prof. Albrecht, from Brussels, developed his views on the morphological significance of the auditory ossicles of the middle ear, of the external ear, and of the Eustachian tube. Respecting the auditory ossicles there had hitherto prevailed two views. There was, first, the German view, represented by Prof. Gegenbaur, according to which the joint between malleus and incus corresponded to the quadrato-mandibular joint of the lower vertebrates, incus answering to the os lenticulare, stapes to the os quadratum, and malleus to the os articulare. The second view was the English one, set up by Prof. Huxley, according to which all four auditory ossicles of the mammalia were homologous with the os quadratum. The speaker considered both views to be incorrect. As to the latter, the four auditory ossicles of the mammalia, seeing they lay between the fenestra tympanica and the fenestra ovalis, must in his opinion be the homologue of the columella of the reptiles, amphibia, and birds, which likewise extended from the fenestra tympanica to the fenestra ovalis. The columella itself was the homologue of the symplectico-hyomandibulare of the fishes. The auditory ossicles had nothing whatever to do with the quadrato-mandibular joint. The os quadratum of the lower vertebrates must, on the contrary, be sought for at an entirely different place, in the lower part, namely, of the pars squamosa of the temporal bone. At this place Prof. Albrecht had in point of fact observed in different cases fissures by which the superior part was separated from the zygomatic part, the proper os quadratum. The middle ear was, in the opinion of the speaker, divided by the columella into two sections, of which the anterior, the precolumellare, was, through the Eustachian tube, brought into connection with the larynx, and, through the anterior part of the tympanum, with the external organ of hearing. This whole section of the ear was, according to the view of Prof. Albrecht, the remains of a special pharyngeal gill-segmentation.—Prof. Flesch, as guest, communicated some results of his investigations into the peripherical nervous cells. The question of the histological diversity of the nerve-cells, which, by the labours of Stieda, had been solved in a negative sense, had again been taken up by Prof. Flesch. In order to a settlement of the question, he had applied himself to the peripherical nerve-cells and to different methods of staining. It was the colouring method with Weigert's hæmatoxylene and treatment with osmic acid which especially yielded beautiful results. The osmic acid had been used on quite fresh preparations, at most five to ten minutes after the death of the animal. The fact at once established itself that the nerve-cells, under precisely the treatment and under perfectly the same conditions of experiment, showed variations which were not artificial products. It was, first, possible to distinguish between stained and colourless cells. The former were mostly small, the latter large. The relation of the large pale cells to the small dark cells was a perfectly constant one, and that even in the case of different animals. In the peripherical ganglia the pale cells constantly amounted to 20 per cent., the dark to 80 per cent. In the spinal marrow, on the other hand, the number of the pale cells invariably amounted to about 40 per cent. On further investigation it came out that little colourless cells also occurred in small number. The occurrence of these differences among the nerve-cells under use of the most varied staining means and in various animals, especially, however, the determinate numerical relation of the various groups of nerve-cells in the peripherical ganglia and in the spinal marrow, were deemed by the speaker to be proofs that there was here a question of physiological variations. This difference might be of manifold significance. In the first place there might here be a question of various stages of development on the part of the nerve-cells—young, adult, and senile forms. In the second place the various forms might be the expression of a different nature on the part of the nerve-cells: one set being, possibly, motory, another sensory, and so on. In the third place and lastly, these various forms might, in a manner similar to what had been observed in the glandular cells, be the expression of different states of activity or of rest on the part of the nerve-cells. By way of arriving at a decision among these different possibilities, Prof. Flesch had had a series of experimental investigations undertaken which had not yet come to a conclusion. The probability, however, was that the experiments in question pointed to functional variations on the part of the nerve-cells which were the subject of investigation.

A HAND-BOOK TO THE HISTORY OF PHILOSOPHY

A Hand-Book to the History of Philosophy. For the Use of Students. By Ernest Belfort Bax. Bohn's Philosophical Library. Pp. 405. (London: George Bell and Sons, 1886.)

THE task to which Mr. Bax has set himself in writing a short and at the same time intelligible account of the history of philosophy is anything but an easy one. The historian of philosophy finds himself in presence of an enormous amount of material, which has accumulated as system has followed system in what at first sight seems a bewildering succession. It will naturally occur to the reader to ask whether after all the history of superseded systems of philosophy is of much more than antiquarian interest, or whether at best its study can be expected to repay the necessary trouble.

There is a pretty widespread idea that philosophy, or "metaphysics," has led to nothing but disappointing failures in the past, and cannot from its very nature lead to any result of real value. This idea would appear to depend on a radical misconception as to the nature and scope of philosophical inquiry. Those in search of first principles in any department of science cannot fail to come across questions which they find cannot be solved by the methods which may be applied to the ordinary questions occurring within their science. Such questions occur naturally and necessarily in mathematics, physics, biology, art, &c., and in virtue of their similarity may be all classified as philosophical questions. As a familiar example we may take the question, which must necessarily come prominently before the physiologist, as to whether consciousness is a function of the body. It is pretty generally acknowledged that this question cannot be solved by experimental methods. The question is a philosophical one, and can only be attacked by the method of philosophy.

Let us see what this method is, and how it is to be applied to the case in question. Mr. Bax defines philosophy as the result of the endeavour to reconstruct the world according to its possibility. Applying the method here indicated we have to ask whether it is possible to conceive the world of our experience on the supposition that consciousness is a function of the body. This was substantially the question which Locke set himself to answer; and it was finally answered by Hume, who showed that the supposition in question led necessarily to its own annihilation. It remained for Kant and his successors to point the way to the only hypothesis consistent with the facts.

Such being the scope and method of philosophy, we may readily understand that its history is no mere record of an arbitrary series of speculations successively displacing one another, but never leading to any permanent result. Modern philosophy has centred round the discussion of the relation of matter and thought; and its successive systems form so many landmarks in the progress towards a solution of the fundamental questions involved in this discussion. Each system is doubtless more or less burdened with superfluities and errors of detail; and many philosophical works have been written by men famous in their day, but who failed to realise the true position of philosophical thought in their time, and thus cannot be assigned a permanent place in the history of philosophy.

Progress in philosophy is nevertheless just as well marked as in any department of science; and it is the special merit of Mr. Bax's hand-book that this progress is everywhere clearly brought into prominence.

There is one important respect in which the history of philosophy differs from that of any of the sciences, and which gives it a far greater relative importance. The detailed results of a science have a value of their own more or less independently of theoretical considerations or of other facts of the science in question. Thus the experimental results of chemistry have each a value independently of the truth of the vast majority of the other experimental results of the science, and even of the atomic theory itself. In philosophy, on the other hand, the conclusions arrived at are closely interdependent, and have no value apart from the general conception to which they belong, and the process by which that conception has been arrived at. It is as if the conclusions of chemistry were entirely valueless apart from the atomic theory and its correct application in detail. If this were so, it is evident that the history of the atomic theory and its application would be the first essential for the student of chemistry, instead of being what, as a matter of fact, many students of chemistry have only a very hazy notion of. Philosophical conclusions may be said to include the process by which they have been arrived at, so that a knowledge of the history of philosophy is in reality the basis of all study of philosophy. For this reason it will probably only lead to perplexity and disappointment to attempt the study of any philosopher without knowing the point at which he took up the work of his predecessors. Just as the individual organism shadows forth in its own development the forms assumed in the evolution of the stock to which it belongs, so the student of philosophy must repeat in his own mind the essential points in the historical development of philosophy.

A detailed criticism of Mr. Bax's work would scarcely be in place here. The book is on the whole an excellent piece of work. It is less of a summary, and much more readable, than the similar work of Schwegler, and for this reason will probably be preferred by English students. Due weight is as a rule given to the elements in any philosophical system which were of permanent value in influencing subsequent thought, while systems which were in reality anachronisms, however much stir they may have made, are passed over rapidly.

There are few positive blots in the book. One of these, cropping up in one form or other at various places, consists in the writer's persistent identification of the "anti-worldliness" of Christianity with "other-worldliness." As regards this and other kindred subjects the candour of Mr. Bax's expressions of opinion will, however, thoroughly commend themselves to the reader.

J. S. HALDANE

ELECTRICITY TREATED EXPERIMENTALLY

Electricity Treated Experimentally. By Linæus Cumming, M.A. (London: Rivingtons, 1886.)

THOSE who are acquainted with Mr. Cumming's "Introduction to the Theory of Electricity" will welcome most heartily a new and excellent little work from his pen. The book before us is on "Electricity Treated Experimentally"; and it is highly to be commended. It is admirably clear and concise, and at the same time the information is full and is well arranged; while the multitude of excellent illustrations and the open double-leaded type make the little book very pleasant and satisfactory reading.

The portions devoted to magnetic and electric measurements, both electro-static and electro-kinetic, are, as we should expect from the author, clear and full; while the descriptions of the various measuring instruments are very satisfactory. An excellent account is also given of Faraday's experimental investigations in electro-statics and electro-magnetism, and of those of Ampère in electro-dynamics.

The least satisfactory portion of the book is the chapter headed "Current Induction." This chapter, even making all allowances for its necessary brevity, requires very considerable improvement and amendment. The descriptions given of dynamo-electric machines are very far from adequate, even to the extent of making little or no distinction between a magneto-electric machine and a so called "dynamo." Under the heading "Siemens Dynamo" there is a description and diagram of the old Siemens shuttle-wound armature; and Fig. 218, which is a diagram of a Gramme magneto, shows the soft iron of the armature cut away almost to nothing to make space for the armature. The information given with respect to the incandescent lamps and incandescent lighting also requires improvement to make it suitable for the present day; and the description of the telephone and of experiments to illustrate the action of it are not satisfactory. Some of these instruments it is perhaps unnecessary to treat of in a book of this class; but if they are dealt with at all the treatment must be correct and not too meagre.

One or two other minor matters we cannot avoid mentioning. The first is the naming of the magnetic poles. It is greatly to be desired that strong efforts should be made by all teachers to get rid of the English "north" and "south." Most writers of importance are doing this now; either by adopting "blue" and "red" for *true* north and *true* south respectively, or else by using in full the designations "true north" and "true south." However this may be, the practice of marking the ends of a magnet + and − seems to us thoroughly objectionable.

Next we would call the author's attention to the fact that the rule which he has called Oersted's rule for finding the direction in which a magnet turns under the influence of a current is commonly, and we believe rightly, called Ampère's rule. But it would be of very great advantage if Ampère's rule were improved out of existence, and some such rule substituted as that "terrestrial currents *supposed* to correspond with terrestrial magnetism follow the sun." When the unfortunate student imagines himself lying on his face, or (?) back, with a current entering by his feet, or (?) head, and stretches out his right hand, or (?) left, to show the direction of the deflection of the magnet, the probabilities against his coming at the end of his imagining to a correct conclusion are considerable. It seems strange that such a rule should have held its place from Ampère's time till now.

Lastly, we miss the name of Cavendish and his proof (by means of the experiments of Faraday so well described) of the electro-static law of the inverse square of the distance. It is impossible, by means of the torsion-balance, to give anything but a rough proof of this great law. But Cavendish established mathematically that no other law than that of the inverse square of the distance will account for the whole electric charge being found on the outside of a closed conductor; while the experiments of Faraday established to minute accuracy this celebrated law of electric distribution. In searching for the name of Cavendish, too, an alphabetical index would have been of much assistance. It is sad for a reviewer to take up a book without an index! No book, unless it be a novel, should be without one. For small books it is easily made; for large books it is essential.

With these criticisms we must take our leave of Mr. Cumming's book; but we cannot do so without remarking once more that it is one of the pleasantest and most thorough little books on electricity and magnetism with which we are acquainted.

J. T. B.

OUR BOOK SHELF

Constructive Geometry of Plane Curves. With Numerous Examples. By T. H. Eagles, M.A. Pp. xx., 374. (London: Macmillan and Co., 1885.)

THIS book differs considerably from previous treatises on practical geometry. The author has made a serious attempt to improve the instruction usually given in his subject, and the result is that we have a text-book which will lend itself to class-teaching of a thorough and searching character.

Hitherto much time has been spent on constructions which furnish no mental discipline. In this treatise the proofs of the methods used are given or indicated in every case.

A valuable collection of examples is supplied at the end of each chapter. If a numerical result is involved, the answer is usually appended, and hints are given towards the solution of the more difficult examples.

Two-thirds of the book is devoted to conic sections, and herein we find methods of drawing these curves under almost any conceivable conditions; there are also chapters on reciprocal polars and the anharmonic properties of conics which will give the draughtsman some indication of the power of modern geometry and of its usefulness in practical application.

After a chapter on conics as derived from plane sections of a cone, we have about 100 pages devoted to various other curves which are of interest in mechanics or physics. Compared with the exhaustive treatment of the conic sections, the account of several of these curves is somewhat scanty.

We should like to see more space given to equipotential curves, for instance, and to have further exemplification of the methods of construction adopted by Rankine and Maxwell.

The book closes with an interesting chapter on the graphical solution of quadratic equations and certain trigonometrical equations.

Scientific Memoirs by Medical Officers of the Army of India. Edited by B. Simpson, M.D., Surgeon-General with the Government of India. (Part I., 1884). (1) On the relation of cholera to Schyzomycete organisms, by D. D. Cunningham. (2) On the presence of peculiar parasitic organisms in the tissue of a specimen of Delhi boil, by D. D. Cunningham. (Calcutta, 1885).

IN the first of these memoirs Dr. Cunningham makes some interesting additions to our knowledge of the presence and distribution of comma bacilli in the intestinal contents in cases of Asiatic cholera; on the occurrence of peculiar comma bacilli associated with the scum formed on tank water by Euglenæ; and on certain modifications in morphological and other characters in artificial cultivations of the choleraic comma bacilli.

The second memoir gives a minute description of the anatomical nature of the skin disease known as "Oriental sore" or "Delhi boil." This description is the more valuable as it is the first accurate account that we possess of the minute anatomy of this interesting malady. The value is enhanced by the discovery by Dr. Cunningham in the diseased tissue of a peculiar fungus bearing the characters of Mycetozoa or Myxomycetes, more especially of the subdivision of the Monadinæ; the distribution of this fungus is such that a causal relation of it to the disease process becomes highly probable.

The memoir is illustrated by numerous fine lithographs, many of them coloured. E. KLEIN

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On the Thomson Effect as Expounded by Prof. Tait

AMONG modern expositions of the subject of thermo-electricity there is none so full, and on the whole so instructive to students, as that contained in Prof. Tait's "Heat." It is therefore the more important to call attention to what appears to me to be, to say the least, a very questionable statement there made. It refers to the Thomson effect.

Thomson's experiments were of the following nature. A metallic bar was surrounded with a hot-water jacket in the middle and with cold-water jackets at the ends, and there were two holes sunk in it for the insertion of thermometers, midway between the hot jacket and the two cold jackets. When the flow of heat had become nearly steady, a steady current of electricity was sent through the bar; and, after it had flowed for several minutes in one direction, it was reversed; then, after the same number of minutes, it was again reversed, and so on several times. It was thus found that, when the bar was of copper, the current made the temperature of the further thermometer higher than that of the near one (the words *far* and *near* being used with reference to the end at which the current entered). When the bar was of iron, the current made the temperature of the near thermometer higher than that of the further one.

Seeing that a current may be regarded at pleasure as the flow of vitreous electricity in the nominal direction of the current, or as the flow of resinous electricity in the opposite direction, Thomson summed up his results by saying that "the vitreous electricity carries heat with it" in copper, and "the resinous electricity carries heat with it" in iron. He also gave the name of "electric convection of heat" to the effect thus detected. It has since been called by others "the Thomson effect."

The experiments were instituted to test the truth of a conclusion of which he had previously given a theoretical proof—the conclusion that "in one or other of the metals, and most probably in both, there must be a thermal effect due to the passage of electricity through a non-uniformly heated portion of it, which must be an absorption of heat [a cooling] or an evolution of heat [a warming], according to the direction of the current between the hot and cold parts."

It may be taken to be an established fact that, in a uniform linear conductor along which a current is flowing, there is, in addition to the frictional heating, which is proportional to the square of the current, a warming or cooling effect proportional (at given temperature) to the steepness of the thermometric gradient at the point which is warmed or cooled, changing sign with the gradient, and vanishing at points of maximum or minimum temperature, where the gradient vanishes.

Now compare these effects with what happens when a stream of liquid flows through a pipe surrounded at alternate points in its length with hot and cold jackets, the average temperature of the water being the same as the average temperature of the pipe. It will carry heat from the hotter to the colder portions, thus cooling the hottest parts, warming the coldest parts, and at the same time carrying forward the points of maximum and minimum temperature. If, at each point of the pipe (supposed straight and horizontal), we erect an ordinate to represent its temperature, and call the curve of which they are the ordinates "the temperature curve," the effect of the flow of liquid on this curve will be twofold: (1) it will carry the temperature curve forward; (2) it will make the temperature curve flatter.

Thomson's experiments show that an electric current carries the temperature curve forward in copper, and backward in iron; but I am not aware of any evidence to show that it makes the temperature curve flatter.

The analogy between the Thomson effect and convection of heat by a liquid in a pipe therefore does not run on all fours, and must be used with caution.

Maxwell says ("Elec. and Mag.," p. 343, second edition), "positive electricity in copper, and negative electricity in iron, carry heat with them from hot to cold." The words "from hot to cold" are here added to Thomson's original phrase "carries heat with it," and the addition thus made is not in accordance with facts, for it implies that heat is taken away from the hot parts and given to the cold parts; whereas the fact is that heat is taken from parts where the temperature gradient is in one direction, and heat is given to parts where the gradient is in the opposite direction. If the statement be altered by a little transposition, so as to make it stand thus, "positive electricity in copper, and negative electricity in iron, going from hot to cold, carry heat with them," it will be scarcely distinguishable from Thomson's original statement.

Prof. Tait goes further, and says ("Heat," p. 170):—"After a series of elaborate experiments (described in the *Phil. Trans.* for 1855) [it should be 1856] Thomson found that:—

"*An electric current in an unequally heated copper conductor behaves as a real fluid would do*, i.e. *it tends to reduce differences of temperature. In iron it tends to exaggerate them.*"

The italics are Prof. Tait's.

I can find nothing in Thomson's paper to support the assertion that in copper an electric current tends to reduce differences of temperature, though the idea that it does so is naturally suggested by the analogy implied in the phrase "electrical convection of heat."

The statement that in iron the current tends to exaggerate differences of temperature, seems to be completely original on the part of Prof. Tait. It does not arise naturally out of Thomson's dictum, "resinous electricity carries heat with it in iron"; for if we think of resinous electricity as a real fluid flowing through iron, it would tend to equalise differences of temperature in that metal.

The two statements taken together suggest the following line of reasoning as conclusive against them both:—

Let there be the same initial distribution of temperature in a copper and in an iron bar, and currents in the same direction through both. Then the alterations of temperature at corresponding points in the two bars will have opposite signs. Any one who maintains that the warmest parts of the copper are cooled is therefore bound to maintain that the warmest parts of the iron are warmed. But there is precisely the same ground for maintaining that the warmest parts of the iron are cooled, and therefore the warmest parts of the copper warmed. Whatever vitreous electicity can do in copper, resinous electricity can do in iron. We are thus involved in a contradiction if we assume any finite heating or cooling at the hottest parts. And similar reasoning disproves any finite heating or cooling at the coldest parts.

The following formal investigation confirms the view which I have above expressed.

Leaving out of account frictional generation of heat (in other words, the effect which varies as the square of the current, let $\sigma d\theta$ be the heat generated in unit time by unit current in a uniform copper bar, in passing from a section where the temperature is $\theta + d\theta$ to one where it is θ (see Thomson's "Papers," vol. i. p. 246). Let x be distance along the bar in the direction of the current, and c the thermal capacity of unit length of the bar. The heat generated in a short length δx is $-\sigma\frac{d\theta}{dx}\delta x$, and the consequent rise of temperature in this portion is $-\frac{\sigma}{c}\frac{d\theta}{dx}$. This is in unit time. Hence, putting t for time, and v for $\frac{\sigma}{c}$, we have—

$$\frac{d\theta}{dt} = -v\frac{d\theta}{dx}.$$

If the limits of temperature are not very far apart, it is known that σ and c are sensibly independent of θ; hence v may be treated as a constant. The integral of the above equation is then—

$$\theta = F(x - vt),$$

where F is a functional symbol such that $\theta = F(x)$ expresses the original distribution of temperature. The interpretation is that the original "temperature curve" travels forward with velocity v without flattening or any other change of form.

Belfast, May 14 J. D. EVERETT

Scientific Nomenclature

SOME time ago Mr. "John O'Toole," in the columns of NATURE, waged war against that hideous monstrosity *Potential Energy*, and he very aptly summarised his case against this term by saying that it involves, by the very signification of words, "a double remotion from actuality."

A few months ago it occurred to me that to express what is intended by the potential energy of any system the term *Static Energy* is not only logically unobjectionable but specially fit for the purpose. Thus, if a string or a membrane is stretched, a wire bent and twisted, or, generally, a body strained in any manner, the work which it can do against resistance in returning from its state of strain to its unstrained condition is the *Static Energy* of the system in the strained condition. The work which a moving system can do in virtue solely of its motion is, of course, its *Kinetic Energy*.

Thus we have simply *Static Energy* and *Kinetic Energy*, and these terms have the further advantage of harmonising with the ordinary subdivisions of dynamics.

I may add that the term *Static Energy* has received the approval of all the mathematical physicists to whom I have submitted it. GEORGE M. MINCHIN

R.I.E. College, Cooper's Hill, May 19

Pendulum Oscillation

THE oscillations of a long pendulum are observed to describe an ellipse the axis of which tends to set itself at right-angles to the plane in which the pendulum was started. An explanation of the above phenomenon would much oblige. M. H. MAW

Walk House, Barrow-on-Humber, Hull, May 18

What is Histioderma?

Histioderma hibernica was described by Dr. Kinahan in 1858 as an annelid, and most writers who have since mentioned it have also regarded it as such. Dr. Haughton notices and figures it in his "Manual of Geology," Sir R. I. Murchison places it amongst annelids in his "Siluria," as also Dr. Bigsby in his "Thesaurus Siluricus." Writing from memory only, I think a description and figure will be found in W. H. Baily's useful compendium of Palæozoic British fossils, published a few years ago. The fossil is mentioned with more or less detail by numerous writers on Cambrian strata.

The above references will perhaps answer the letter signed "S.," but there still remains the question, What is Histioderma? It is apparently a fossil impression in the rocks of Bray Head, Wicklow, Ireland. Only one species and only one locality is, I believe, known. It seems to me very doubtful what kind of animal made the impression—whether an annelid, or otherwise. I am inclined to doubt if the rocks are Lower Cambrian, as geologists generally suppose, because the evidence seems to indicate that the Bray Head rocks had become hardened and raised into land before the oldest Lower Cambrians of Wales and England were deposited. I would therefore pass on the question and ask, What is Histioderma?

4, Cowper Road, Acton, London, W. A. RAMSAY

IN answer to the above question in your issue of May 20 (p. 53), I refer your correspondent to the *Proceedings* of the Geological Society of Dublin, where he will find (*Natural History Review*, vol. v., *Proceedings* of Society, p. 150) the original description of Histioderma by Prof. Kinahan. According to its author, Histioderma is the tube of a cephalo-branchiate annelid. J. VICTOR CARUS

Leipzig, May 23

Black Skin

IN a letter lately received from Mr. Flinders Petrie, who is now in Egypt, are some remarks on "Black Skin," which I think very interesting, and perhaps the readers of NATURE may think them so too, so I send the paragraph to you.

Belvedere, Kent, May 24 F. C. J. SPURRELL

"In considering the use of a naturally or artificially black skin, we should not look so much to the requirements of the surface, which is constructed to bear variations, and has the means of cooling and maintaining a proper temperature within itself, but rather we should consider the far more delicate tissues beneath. We all know how translucent flesh is to strong light, and it can hardly be doubted that the rays of a tropical sun would light up a white man's inside considerably; whereas black skin would stop out the solar energy of light, heat, and chemical rays effectually. Skin heat is of no importance, as perspiration can always keep that down. May not the oiling of the skin in hot countries be partly to make it reflective, so that it should absorb less heat? And may not the regard white races have for clothing be partly for the purpose of keeping the insides of their bodies sufficiently in the dark?"

Male Animals and their Progeny

CAN any of your correspondents inform me whether any of the male wild animals in foreign countries show any love for, or recognition of, their progeny? In this country amongst the domestic animals it does not seem to exist, save in the case of the gander, who carefully guards the goose while sitting, and attends to the goslings when hatched; but the cock pays no attention to the hen while sitting nor when with chickens, nor does the dog, the bull, the horse, nor the boar evince any sign of parental feeling under circumstances favourable to its development.

One peculiarity of geese is, I think, worthy of notice, for it is not possessed by ducks or fowls, who also live in flocks. If when goslings are hatched, they are permitted to run with a goose in company with the other geese of the flock, all chances of any eggs being laid by the other geese who have no goslings are over. P.

Birds and Mirrors

FOR six days I have been for two or three hours in the club reading-room, where t ere is a large mirror. During all this time a cock and hen sparrow have been flirting with and bowing to their images in the glass with evident pleasure—rushing along the mantel-shelf, flying to the top of the frame, or resting for a time, always apparently happy in contemplation, never showing disappointment. Sind Club, Karachi, May 2

SURGEON-MAJOR T. R. LEWIS

DR. TIMOTHY LEWIS, Surgeon-Major Army Medical Staff and Assistant Professor of Pathology in the Netley Army Medical College, whose death, which took place on May 7, we announced last week, was a native of South Wales, and received his medical education at University College, London, and graduated as M.B. at Burlington Gardens. He was selected about twenty

years ago, together with Dr. Cunningham, to proceed to India in order to undertake, under the auspices of the Indian Government, a prolonged study of the causation of cholera, especially in regard to its reputed relation to parasitic organisms. At that time little was known or thought about Bacteria, and the public mind had been aroused by Hallier's (now long-exploded) theory of a rice-fungus as the cause of cholera, just as more recently it has responded to Dr. Koch's invitation to believe in the comma-bacillus. Dr. Lewis and his companion were authorised to visit Prof. Hallier at Jena and Prof. de Bary (in those days not attached to French Strasburg!) for the purpose of acquainting themselves with methods of mycetological research before proceeding to India. A few weeks was all the time allowed them for this visit, and consequently they took little to India excepting their own conscientious habits of work and that modicum of knowledge of microscopic *technique* which was considered sufficient for the highest medical qualification in England in those days. Nevertheless these observers made most valuable and minute researches on the microscopic organisms present in the dejecta of cholera-patients, which were published by the Government of India. Dr. Lewis extended his researches into the general question of the presence of microscopic organisms in the blood and tissues of man in health and disease, and was led to some very interesting discoveries. His results were published from time to time by the Government of India, and were re-published as they appeared in the *Quarterly Journal of Microscopical Science*.

Dr. Lewis's work was always remarkable for the extreme care with which positive results were asserted, and for the fairness with which the researches of predecessors in the same field were considered and discussed. His most remarkable discovery was that of the little nematoid worm occurring in the blood of persons suffering from a form of chyluria and elephantiasis, to which he gave the name *Filaria sanguinis hominis*. This discovery was published in 1872. Some years later Dr. Bancroft discovered in Australia the adult worm from which the brood of minute blood-parasites is derived, and, still later, an unsuccessful attempt has been made by Dr. Patrick Manson to show that the young pass an intermediate stage of existence in the alimentary canal of gnats, which suck them in together with the blood of worm-infested persons.

It is no small thing in these latter days to discover a new human parasitic worm of great pathological significance, and it was in recognition of this discovery, as well as in view of his important contribution to the discussion of "the cholera-bacillus theory," that the Council of the Royal Society in last April selected Dr. Timothy Lewis as one of the fifteen candidates to be submitted to the Society for election in next June.

In regard to the question of the relation of Bacteria to cholera and similar diseases, Dr. Lewis had a vast store of both published and unpublished observation. With characteristic caution and modesty, he had refrained from dogmatising on the subject. Working for twelve years in Calcutta, with daily access to cholera patients, he was thoroughly familiar with the several different forms of Bacteria which are to be found in the alimentary tract and in the dejecta of choleraics. Unlike some of his recent successors in this line of research, Dr. Lewis was also familiar with the different forms of Bacteria which occur in the *healthy* human mouth and intestines, and in potable waters. He was therefore able to demonstrate immediately on the publication of Koch's figures of the so-called "comma-bacillus" that this *form* (asserted by Koch to be peculiar to cholera evacuations) was nothing more nor less than a *Spirillum* broken by manipulation, and commonly to be found in the mouth of healthy persons. The importance of this contribution to the controversy excited by Dr. Koch's statements cannot be too highly estimated. Its accuracy was universally recognised at once, and has never been called in question. Dr. Klein has since come to the conclusion that not only are organisms of the exact *form* of Koch's cholera-comma abundant in the healthy saliva, as shown by Lewis, but that some of these forms have precisely the same physiological conditions of growth, and precisely the same action upon gelatine as Koch considered to be characteristic of those obtained from cholera evacuations.

At the time of his death Dr. Lewis was carrying on in his laboratory at Netley an extensive series of culture and inoculation experiments, chiefly upon the Bacteria which occur in the alimentary canal of man.

Those who enjoyed his personal friendship valued Dr. Lewis for his warm-heartedness no less than for the rare combination of enthusiasm with caution in his work which gives his published results a very special value. It is perhaps some satisfaction to his friends to know that he had heard of the recognition of his merits by the Royal Society Council before the commencement of the attack of inflammation of the lungs which so rapidly ran to a fatal termination. E. R. L.

A SKETCH OF THE FLORA OF SOUTH AFRICA

UNDER this title we would draw the attention of botanists to a very able essay on the botanical regions of South Africa, contributed to the "Official Hand-Book of the Cape of Good Hope" for 1886, by Harry Bolus, F.L.S., an accomplished botanist, who has devoted many years to the investigation of South African plants.

That extra-tropical South Africa is one of the most varied botanical regions on the globe is a fact familiar to both botanists and gardeners, from the days of Linnæus,—who epitomised its richness in the expression, "Ex Africâ semper aliquid novi,"—and of the earliest cultivators of greenhouse plants, who were indebted to the Cape of Good Hope, far more than to any other regions of the globe, for what were, and till Japan and Australia eclipsed it, the prime favourites of the conservatory. There are those still alive who can remember the time when plant-houses were ornamented with little else than Cape Heaths, Pelargoniums (miscalled Geraniums), Polygalas, Proteas, Oxalis', Mesembryanthemums, Everlastings, Stapelias, Irideæ, and Cape bulbs innumerable, and when the illustrated horticultural serials of the day were either devoted to these, or contained figures of more of the plants of this than of any one other country. It is true that the cultivation of all but a very few of the heaths and geraniums has been abandoned for things of not greater beauty, and of far less interest, but this is due, not to want of appreciation, but in the case of some to their not being amenable to the treatment of the "soft-wooded" plants now in vogue, and of others to the fact that their flowering period—of the bulbs especially—is a very brief one, and that the flowers soon fade when cut.

To return to the little essay before us: the attempt to define the South African regions of vegetation is not a new one; it had been essayed by Meyer and Drège, Zeyher, Griesebach, and others, but not successfully; and the author of the sketch under consideration is the first who has succeeded in presenting satisfactorily the salient botanical characters of that flora, as affected by, or in correspondence with, geographical and other physical conditions; whilst he alone has given such vivid pictures of the vegetation of the different botanical regions he has defined, that any one with even an elementary knowledge of South African plants can fancy himself travelling over the ground.

The two dominant features of the South African flora are, the number of orders, genera, and species that it contains, and the limitation of great groups of these

within very narrow and well-defined areas. There are five of these areas, differing from one another in the aspect as well as in the composition of their floras more decisively than do any other five contiguous areas of similarly small extent on the surface of the globe. These five together have been estimated to contain the extraordinary number of 14,000 species of flowering plants! which are comprised under 200 natural orders (nearly three-fourths of the known orders of plants), and 1255 genera (one-sixth of the described genera of the whole world). Though possessing no truly Alpine region, it is by far the richest extra-tropical area on the globe in respect of genera and species, and is probably not surpassed by any tropical area of equal extent; a circumstance which may be taken together with the fact, that the vast proportion of the species are low herbs or small shrubs—trees being very rare both in species and individuals, and that there is not a single arboreous genus of more than a very few species. There is no dominant genus of trees like the Eucalypti of Australia and the Conifers of northern regions, or even the oaks or beeches of Europe, that monopolise great areas and determine the absence or presence of a multitude of plants of lower stature. The following are Mr. Bolus's regions:—

(1) *The South-Western Region.*—This (which might be called the Cape proper region) extends in a curve from near the mouth of Olifant's River along the coast facing the Western Atlantic, round by the Cape of Good Hope to Cape Agulhas, and thence to near Port Elizabeth along the coast facing the Southern Atlantic. Throughout its length—about 600 miles—it maintains a breadth of between 40 and 80 miles, never more or less, and is bounded on its landward sides by mountain-ranges attaining 4000 to nearly 8000 feet in elevation—of which the eastern run east and west, the western north and south. The surface is varied with bushy, grassy, sandy, and rocky tracts, of which some appear desolate from a distance, but on examination are found to swarm with genera and species. It is a region of small-leaved herbs and bushes—of Irideæ, Orchideæ, Rutaceæ, Ericeæ, Restiaceæ, Compositæ, Proteaceæ, Polygaleæ, Mesembryanthemums, Oxalideæ, Geraniaceæ, and Leguminosæ It is that whence all the Cape plants of the greenhouses of the last generation were derived. The climate is dry, temperate, and comparatively equable, with a winter rainfall which varies excessively from 24 inches at Cape Town to 60 in some of its own suburbs, but everywhere rapidly diminishing with distance from the coast and from the vicinity of Cape Town. The few forests are near the few rivers, and their trees rarely exceed 50 feet in height. As an instance of the endemic nature of its vegetation, the genus Erica forms one of the many conspicuous examples. It contains no fewer than 300 Cape species; all, or nearly all, are confined to this region, and various other genera contain upwards of 100 endemic species. The total number of flowering plants in this region is about 4500. No temperate area of the globe of its extent is nearly so peculiar or rich. California offers but a faint counterpart; and the restriction of the majority of the species of Cistus and Ulex to the Atlantic coasts of Europe offers an even fainter example of restricted distribution.

(2) *The Tropical African Region* (which might be called the Natal region).—Unlike the western temperate coast, the vegetation of the eastern temperate retains the characteristic features of that of tropical Africa. From Port Elizabeth northwards to Abyssinia there is no sharp delimitation of floras. This region is bounded on the east and south-east by the Atlantic, and stretches inland for from 60 to 100 miles to ranges of mountains of 5000 to 10,000 feet high, which bound it on the west. The surface is varied with bush and park, which, proceeding northward, give place here and there to extensive forests, and it is traversed by many streams. The herbage, and bush- and tree-foliage, are greener than in the south-western district, and the foliage larger. The rains are summer ones, the temperature rather higher than in the west, and much more so to the north. Though there is some overlapping of the vegetations of this and the Cape region proper in the neighbourhood of Port Elizabeth and Grahamstown, the transition from one to the other is wonderfully sudden. The 300 heaths may be said to disappear bodily, as do the Cape Rutaceæ, Proteaceæ, and Orchideæ. As suddenly appear giant Cycadeæ, Aloes, leafless succulent tree Euphorbias, with different tribes of Orchideæ, Leguminosæ, and Amaryllideæ, often grouped in striking assemblages of grotesque forms, whilst a palm, *Phœnix reclinata*, reaches lat. 33° S. Along with African types, Indian abound, both in genera and species, especially to the northward.

(3) *The Karroo Region.*—Returning now to the Western Atlantic coast of South Africa, from Olifant's River to the Orange River, and thence south-eastwards, bounding the Cape proper region on the north, extends a vast shallow basin about 2000 feet above the sea-level, except towards its western or littoral boundary. It forms a curve somewhat concentric with that of the Cape region proper, and extends a little further east into the tropical African region. It is about 700 miles in length, and from 30 to 70 in breadth from the bounding mountains on the north, which are the Nieuveld Bergen, to lower ranges on the south. The surface consists of sandy, stony, or fertile plains of vast extent, traversed by river-beds, and by the courses of torrents filled by summer thunderstorms, but dry in winter. Permanent water is scarce, and (as in California) sheep have denuded large areas of native vegetation. The climate is excessive; the rainfall, chiefly a summer one, from 7 to 14 inches according to locality. During the dry season the country is a desert, but after a shower it is suddenly, but transiently, transformed into a vividly-coloured garden.

"I was amazed on visiting that desert country, after the rains of June to July 1883, to see tracts, hundreds of acres in extent, covered with sheets of living fire or glowing purple, visible from several miles' distance, caused by the beautiful Compositæ in flower; and nothing is more curious than to see this luxuriance intermingled with the black or white branches of dead shrubs killed by previous droughts, standing like ghostly intruders on a scene of merriment and joy. These charming scenes pass away all too rapidly, and in a month or two little that is beautiful remains."

The only tree is the ghastly *Acacia horrida*, fringing the dry river-beds. Of the Orders of the Cape region proper, Ericeæ, Restiaceæ, Polygaleæ, Orchideæ, Proteaceæ, Rutaceæ, almost all are absent, and a variety of so-called succulent plants appear, especially innumerable species of Mesembryanthemum, together with Portulaceæ, Zygophylleæ, Crassulaceæ, Stapelias, Ficoideæ, and dwarf Euphorbias, besides which many other genera that are never succulent elsewhere, here have species with fleshy roots, stems, or leaves. The tree Aloes of the Eastern region are fairly well represented, but by different species, and the same remark applies to the Geraniaceæ of the Cape region. The curious Elephant's-foot (Testudinaria) is a characteristic plant, as are the two species of the parasitical Rafflesiaceous genus Hydnora, which extends to Abyssinia.

(4) A very singular region or subdivision of the Karroo region is called by Mr. Bolus the "Upper Karroo," or "*region of Compositæ*," which occupies an inland broad area north of the Karroo region, everywhere distant from the coast, about 400 miles from east to west, and 150 to 200 miles in breadth. It is a mountainous country, only partially explored, and supposed to have a mean elevation of 4000 to 5000 feet. Its prevalent features are that of a treeless, heathy tract, or dry elevated moorland, covered with shrublets of a dull hue. The climate is severe, the summer nights are always cool, sharp frosts are common,

and snows falls in winter. Compositæ abound. Of nearly 1000 species that have been collected in this region, 61 genera and 231 species are referable to this Order. Of Orchids only four species have been found; Rutaceæ, Ericaceæ, and Restiaceæ are all but absent, and Proteaceæ wholly so.

(5) *The Kalahari Region* is the name Mr. Bolus gives to the vast tract of country north of the Composite region, west of the Natal region, and south of the tropic of Capricorn. It is a desert country, with an extreme climate, a rainfall of summer thunderstorms, hot summers with cool nights, and frosts in winter. Its essential features are of a country clothed with grass in tufts, and isolated shrubs and trees, which form forests in the north, and are thus probably continuous with the forests of tropical Africa. The Cape flora has here disappeared, and with it we take leave of Mr. Bolus's very able and most interesting contribution to botanical geography, regretting that want of space prevents any notice being taken of the many valuable observations and comparisons that he has made relating to the affinities of the South African with the Australian flora, and other matters of scientific interest. J. D. H.

THE INTERNATIONAL COMMITTEE OF WEIGHTS AND MEASURES

THE Comité International des Poids et Mesures, which has its bureau at Sèvres, has recently issued its ninth Report to the contracting Governments. The Report gives an account of the work done by the Committee during 1885, and a statement of the probable expenses of the Committee for the current year. During the last year new instruments for the accurate comparison of standards of the metric system have been obtained at a cost of about 500*l*., making a total cost of about 7000*l*. for instruments supplied to the Bureau. For the present year the expenses of the Bureau are estimated at 100,000 francs (4000*l*.), the annual expenditure of the Committee being limited by the Convention to that amount, of which sum about 2650*l*. is for payments to various officers of the Comité. These expenses are divided amongst the twenty contracting Governments, the annual contribution of Great Britain and Ireland amounting to about 300*l*. The new instruments include a comparator for measures of length by M. Brunner; new mercurial thermometers by M. Tonnelot; an air thermometer by M. Golaz; a spherometer by M. Brunner; and other measuring instruments by MM. Oertling, Boudin, Alvergniat, Simmen, and the Société Genevoise.

In the fourth volume of the *Travaux et Mémoires* of the Bureau (Paris, Gauthier-Villars, 1885) reference was made by the Director of the Bureau to the work then in progress, and in the present Report a summary is given of the whole work done by the Committee during the past twelve months.

The work of the Director has specially included the verification of the lengths and coefficients of expansion of several standard metres, and the determination of the weights and specific gravities of several standard kilogrammes for different Governments and scientific authorities. A report is given on the comparison of the new kilogramme prototype (K. III.) with the old kilogramme des Archives, and also on the verification at Paris, by Dr. J. Broch and Mr. H. J. Chaney, of certain British standards. During the present year the Committee report that Dr. Broch will continue his researches on the influence of light on the defining-lines of standards of length, and M. Benoit will also carry on his experiments on the best means of comparing end-measures of length (*mesures à bouts*) with line-measures (*mesures à traits*). Dr. Thiesen will continue his interesting studies on balances and the verification of kilogramme standards. Dr. Chappuis, with the assistance of Dr. Guillaume, will also continue the experiments on the verification of thermometers.

It would appear that the Committee are carrying out the duties intrusted to them with all possible care and despatch. In the preparation of the alloy of platinum-iridium, of which the standards of the kilogramme and metre are made, extraordinary difficulties were originally encountered, owing mainly to the presence in the iridium of iron, rhodium, ruthenium, osmium, and other metals, and the Committee therefore obtained the assistance of MM. Stas and Debray. The report of these eminent metallurgists shows that the Committee are indebted to Mr. G. Matthey for the production of an alloy having the high purity and finish required for such work.

The Report of the Committee includes copies of its correspondence with the different contracting Governments. In an able note to the Japanese Minister, Dr A. Hirsch (the Secretary of the International Committee) explains the objects of the Metric Bureau, and it is gratifying to find that Japan has now joined the Convention. From the correspondence with this country it would appear that our Government will in due course obtain copies of the new metric standards.

The Committee announce that the vacancies caused by the death of Prof. Heer and the resignations of Gen. Wrede and Dr. Gould have been filled by the election by the Committee of Prof. Th. v. Oppolzer, Mr. W. H. M. Christie, and Prof. Thalèn.

The Report also includes copies of a correspondence with reference to a proposal made by the French Government to extend the functions of the Bureau to the determination and verification of electrical standards of resistance and light, for the use of the different Governments. The proposal appears to have gone no farther at present than asking the several contracting Governments whether they would have objection to the preparation of estimates showing the cost of a new or extended Bureau for electrical purposes. The replies of Belgium, Denmark, Spain, the United States, Italy, Servia, and Switzerland are attached, but, excepting Spain and Switzerland, it cannot be said that generally the Governments appear to have given the proposal the most cordial welcome.

THE WEATHER OF THE ICE SAINTS' FESTIVALS OF 1886

LAST year we chronicled (NATURE, vol. xxxii. p. 62) one of the most disastrous snowstorms that ever occurred at this season in Vienna, where, on May 15, there fell $5\frac{1}{2}$ inches of snow, and the cold accompanying the storm was so intense that several persons who were exposed to it were frozen to death. Over Austria and Hungary snow covered the fields and vineyards, and, the crops being in a somewhat advanced condition at the time, an incalculable amount of damage was done. But the festivals of the Ice Saints (May 11, 12, and 13) this year have been marked off for a wider and deeper remembrance by storms of wind, rain, hail, and snow in all the continents of the northern hemisphere, which, for number and destructiveness, are perhaps unexampled at this time of the year.

In the British Islands the cold acquired its greatest intensity on the five days from May 11 to 15, and was coincident with a system of pressures which appeared in the Channel, and thence proceeded in a north-north-easterly direction through the North Sea to the south-west of Norway, which was reached on the 15th. It necessarily resulted from this distribution of pressure that northerly and easterly winds prevailed in these islands, and temperature fell correspondingly low. Over that

large portion of the British Islands lying between lat. 52° and 58°, the mean temperature of the five days was at least 6°·0 under the average of the season, and in the central portion of this district, as at York and Barrow-in-Furness, it was 8°·3 under the average. On the other hand, in Jersey the defect from the mean was only 1°·5, and in Shetland 2°·5. At Barrow-in-Furness, on the 12th, the maximum temperature was only 39°·0. On this day snow fell over the higher districts of central and southern Scotland, in many places to the depth of several inches, and the cold was so intense that swallows and some other birds perished in thousands.

Meanwhile torrents of rain were being poured down continuously over wide districts of northern and central England. These rains were heaviest and most widespread on the 11th, 12th, and 13th, on each of these days upwards of an inch being recorded in many places. Mr. Scott states in the *Weekly Weather Report* that during these three days falls of 4·83 inches occurred at Churchstoke, Montgomeryshire; 4·36 inches at Hereford; 4·15 inches at Pershore, Worcestershire; 3·38 inches at Ross, Herefordshire; and 3·44 inches at Fassaroe, county Wicklow. Extensive and disastrous floods were the consequence. The railway traffic between Worcester, Hereford, and Malvern was suspended, and the whole of the united valley of the Severn and Teme, in the neighbourhood of Worcester, was laid under water. At Gloucester large numbers of the inhabitants were driven from their homes. The valley of the Trent presented the appearance of a vast lake, and the Midland Railway between Nottingham and Derby was submerged. Immense damage was done about Chester and along the estuary of the Dee, over the low grounds bordering the Humber, and over extensive tracts of Yorkshire.

A noteworthy feature of the storm is shown in the weather maps for the morning of the 13th, when the area of low pressure extending from west to east over the south of England was broken up, and showed three satellite cyclones with still lower pressures, having their centres the first to the west of Brest, the second over Somersetshire, and the third over Kent,—these all evidencing great, well-marked, and sharp local differences in the distribution of temperature and vapour. Further, a most remarkable satellite cyclone was seen near Perpignan, in the south of France, which in all probability represented the small cyclone or tornado that about seven o'clock of the previous evening wrought such dreadful havoc in Madrid, causing 32 deaths, seriously wounding large numbers, variously estimated from 320 to 520 persons, and wrecking hundreds of houses. The area swept over by the tornado was comparatively limited, but within that area, as in the lower Carabanchel, not a house was left undamaged and many were wholly blown down, and hardly any of the inhabitants escaped uninjured. The storm was preceded by a sultry atmosphere, a heavy bank of black clouds in the north, and torrents of rain, and as so frequently occurs with the tornadoes of America, many buildings would appear to have fallen to pieces from an explosive force from within as the tornado passed overhead.

On the 14th violent cyclones or tornadoes occurred at Krossen, near Frankfort on the Oder, at Linz on the Danube, and at Lonato, near Brescia, wrecking houses, and causing great destruction in other ways; and storms of less, but yet of considerable severity are reported from other parts of the Continent. It is to be hoped that some meteorologist of mark will undertake the discussion of these remarkable storms, so as to lead, if possible, to some knowledge of the peculiar meteorological conditions of Europe out of which they originated. In this discussion no little help will be given by the high-level observatories now established at so many points over Europe.

In the United States on May 11 a tornado passed over Kansas City, Missouri, destroyed the court-house and other buildings, and partly demolished the bridge over the Missouri River, and thence pursued an easterly course to Pennsylvania, killing in its course about 90 persons, and injuring 300. On the night of the 12th terrible destruction was done by tornadoes in Ohio, Indiana, and Illinois. From 4 to 5 inches of rain fell within three hours, fully twenty miles of the Little Miami Railway were washed away, and at Xenia, where the waterspout was most destructive, 36 persons were drowned, 80 injured, and more than 100 houses destroyed. On the 14th another series of tornadoes carried destruction through Ohio and Indiana; and on the 15th a tornado, which appears to have formed on Lake Erie, penetrated 100 miles into Ohio. Its path was about 500 yards wide, and it levelled everything with the ground; killed 41 persons, and injured several hundreds. These, with other tornadoes of less severity occurring in Kansas and elsewhere, are stated to be the most severe and destructive storms or tornadoes hitherto experienced in the United States, and the losses are estimated at about 5,000,000 dollars.

The detailed reports of these remarkable storms will no doubt be prepared and circulated with the fulness and satisfactoriness which characterise the work and publications of the United States Signal Office; and, considering the striking simultaneousness of occurrence of these American and European storms from May 11 to 15, Gen. Hazen would, if the Reports were accompanied and illustrated by international weather maps of the northern hemisphere from May 7 to 16, lay meteorologists under a deep obligation.

CRETACEOUS METAMORPHIC ROCKS

IT is now a good many years since Prof. J. D. Whitney announced the existence of Cretaceous sediments in California which had undergone metamorphism into various crystalline rocks. The attention of geologists is once more directed to that region by the recent work of the Geological Survey of the United States. Mr. George F. Becker, whose admirable monograph on the great Comstock Lode has reflected such lustre on that Survey, has more recently been intrusted with the investigation of the quicksilver deposits of California. This research when completed will form the subject of another monograph in the same great series of publications. But in the meanwhile some results of such startling importance in metamorphism have been obtained that Mr. Becker has published in the *American Journal of Science* a brief preliminary outline of them.[1] It appears that the inquiry into the nature and origin of the rocks in question has been carried on partly by examination of their structure and relations in the field, partly by chemical analysis and partly by the study of microscopic sections. In short, all the appliances of modern geology have been enlisted in the investigation.

The area embraced by the rocks which are stated to have undergone metamorphism is estimated at 3000 square miles. The rocks are determined by fossils to be approximately of Neocomian age. They consist chiefly of sandstone and arkose lying upon and probably for the most part derived from granite. Their quartz-grains are cemented in great measure with carbonate of lime, and there are likewise clastic fragments of orthoclase, plagioclase, biotite, hornblende, and other minerals of the granite. From ordinary unaltered fossiliferous sandstones gradations are traceable into varieties wherein a process of recrystallisation has been set up, but has ceased before the fragmental character has been wholly effaced. In this process one of the first stages is often the resolution of the clastic grains into crystalline aggregates from which new minerals are built up. Thus the quartz-grains have had their surfaces so altered that an envelope of

twinned felspar microliths has formed round them. These bodies lie approximately normal to the surface of the residual kernel, which they actually penetrate like pins set in a cushion. Zoisite also, which is present in nearly all the altered sandstones, as a product of metamorphism, sometimes pierces the quartz from outside. Augite and hornblende have likewise been developed, not infrequently as microliths, which, though grouped together in one common crystallographic outline, are not united.

Further stages of change are described as occurring in certain rocks where the fragmental character, though to the unaided eye still traceable, is found to have been replaced by an entirely crystalline structure, giving rise to rocks which must be classed with the diabases. These masses sometimes have their pyroxene in the form of diallage, and are destitute of olivine, but usually contain much zoisite and frequently also hornblende. Diorites of similar origin occur, sometimes with a predominance of hornblende as in true amphibolites.

The shales are silicified and intersected by innumerable quartz-veins, in which, or projecting from their walls, are frequently abundant zoisite crystals. Yet the metamorphism has not destroyed the microscopic fossils contained in the strata. But the most remarkable example of metamorphism cited by Mr. Becker is the conversion of these same felspathic sandstones into serpentine—an alteration referred to in Prof. Whitney's description of this region. He asserts that field observation conclusively proves the great mass of the serpentine, estimated altogether at more than 1000 square miles, to have been made out of the sandstones, either immediately or through an intermediate granular rock. Sections are seen where sandstone shades off into serpentine, and areas of highly-inclined sandstones pass along the strike into the same rock. In this conversion, the change begins along the cracks, working toward the centres of the included fragments, and producing a structure like that seen in decomposing olivine. The felspar fragments are corroded externally, their cracks being irregularly widened and filled with serpentine which sometimes projects as teeth into the clear felspathic mass. Even the quartz-grains have not been able to resist the alteration, but may be seen with their outer parts replaced by serpentine, which likewise penetrates their interior in long slender green needles. Apatite has also been replaced by serpentine, and the same transformation may be surmised in the case of mica and garnet. Mr. Becker states that chemical analyses and microscopic tests demonstrated that the serpentine diffused through the sandstones and forming the massive exposures is all the same mineral. He will no doubt in due time produce the detailed evidence on which his statements are founded. In the meantime he will of course be prepared for much scepticism and even for angry denial of his results. The careful elucidation of the problem he has attacked cannot but be of enormous service in throwing light upon the vexed question of metamorphism. He claims that the rocks which he has been investigating furnish a colossal example of regional metamorphism of which all the successive stages can be studied. Many thousands of square miles of rock have been subjected to such intense lateral compression that they have been utterly shattered, the average size of the unbroken lumps not being greater than that of an egg. In rocks thus crushed warm interstitial water would have potent chemical reactions. Warm basic solutions are believed to have first been produced, and to have converted the sandstones and some of the shales into holocrystalline compounds containing augite and hornblende. Serpentisation is supposed to have followed at a lower temperature, while silicification came last, as the solutions finally became acid Geologists will await with impatience the appearance of the monograph in which these conclusions are maintained.

THE COMPOSITION OF THE EDIBLE BIRD'S-NEST (COLLOCALIA NIDIFICA)

THE nature of the material which forms the edible bird's-nest has been the subject of some controversy. In 1817 Sir Everard Horne (*Phil. Trans.*, 1817, p. 337) suggested that it is the product of the activity of certain glandular structures which he figures in his paper, and which he associates with the gastric glands. In the "Origin of Species" (6th ed., p. 228) Darwin indorses the view of its being entirely a secretion by the bird, speaking of it as "inspissated saliva," and showing how the amount of saliva devoted to nest construction differs with different species. He mentions in particular a North American species which he says "makes its nest (as I have seen) of sticks agglutinated with saliva and even with flakes of this substance." Writing at about the same time, Bernstein (*Journal fur Ornithologie*, 1859, p. 111) connects the nature of the material with certain developments of the bird's salivary glands, which he says are noticeable during the nest-building season.

On the other hand, it has been maintained by many observers that the nest of this species of swift is constructed similarly to the North American species referred to by Darwin, the chief difference being that instead of sticks the bird uses certain algæ which are found in considerable masses on the walls of the caves which they frequent in the breeding season. Other algæ also have been suggested as those used.

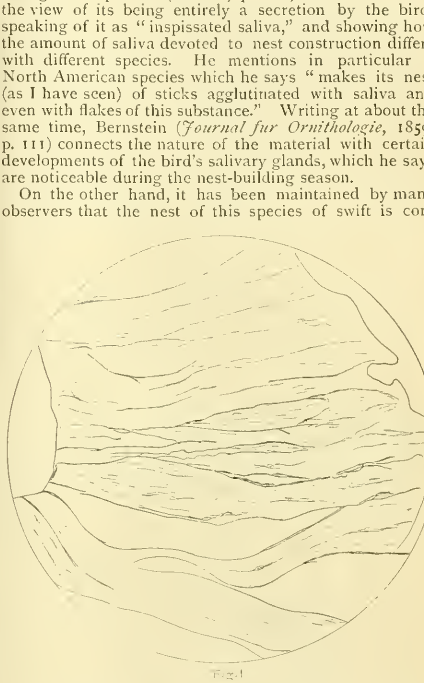

Fig. 1

Celebes nest. Lamellated structure (mag. 50 diam.).

It has further been supposed that the algæ are partially digested before being utilised, and that after regurgitation the material so acted on is worked up into the form of the nest.

A suggestion was made by Mr. E. L. Layard, H.M. Consul in New Caledonia, in a letter to NATURE, September 17, 1884 (p. 82), which seemed to reconcile the conflicting theories. He says that the first quality of nest which is produced early in the breeding season consists entirely of animal secretion, but that later on, if the first nests are destroyed, the birds cannot replace them by this secretion alone, and so use extraneous substances to help in the construction. The second and inferior qualities of nest are so formed differently from the first.

In a paper published in the *Journal of Physiology* (vol. vi. p. 40), I have given the results obtained from an

examination, both microscopic and chemical, of the nests used for soup at the Health Exhibition of 1884. Since then I have had, by the kindness of Mr. W. T. Thiselton Dyer, Director of the Royal Gardens, Kew, the opportunity of examining various specimens of the nests,

Fig. 2

Borneo nest. No alga present (mag. 200 diam.).

obtained from other places than the first-named, and differing from one another in quality.

The results of my experiments on these nests do not modify in any essential particular those which I had obtained before from the first ones examined. After prolonged soaking all alike became gelatinous in texture, and

Fig. 3

Celebes nest. Alga present (mag. 200 diam.).

then were easily seen to be made up of laminæ affixed by their faces to each other. Whether the observation was made by teasing with needles or by cutting sections, this laminated structure was very evident. Fig. 1 is a section of a nest from Celebes, enlarged about 50 diameters. The laminæ are fairly regular in disposition, and show no trace of any vegetable structure between them or in their substance. Here and there may be noted small granular bodies resembling epithelium cells. These are seen more distinctly in Fig. 2, which is a section of a nest of inferior quality from Borneo enlarged 200 diameters.

Another nest, also from Celebes, but marked as being of inferior quality showed the presence of algæ. A section of this, taken from the part where the greatest quantity was found, is shown at Fig. 3, the enlargement being again 200 diameters. The presence of the alga in this inferior nest seems at first to bear out Mr. Layard's suggestion, but an examination of the mode in which it is disposed in the nest-substance does not confirm his view of its being here even an agglutination of alga because the supply of saliva had failed. The alga-cells, though fairly numerous, are not in large quantity when compared with the amount of nest-substance, nor are they regularly placed in layers as would be the case if agglutinated as suggested. Their somewhat scanty amount and their irregular position would be better accounted for on the theory of their being accidental constituents. In many sections debris of one kind or another mixed with the secretion is not at all infrequent, small feathers being the most numerous. In the nest in question the alga was not present throughout, many sections showing none, others a little, the quantity varying very much. The amount found may perhaps be connected with the feeding of the birds, and result from debris of food remaining in the mouth, and so mixed up with the secretion next produced.

The nest-substance gave no micro-chemical reactions that could connect it at all with cellulose, so that it could not be formed by the partial digestion of the alga and regurgitation of the resulting matter. On the other hand, it did give very striking evidence of its close relationship with the body *mucin* described by various authors,[1] and well known as a product of the animal body. The reactions obtained with the first material used (that from the Health Exhibition) were confirmed completely by the experiments made upon the nests from Kew.

JOS. R. GREEN

Physiological Laboratory, Cambridge

NOTES

MR. ADAM SEDGWICK, M.A., Fellow and Lecturer of Trinity College, Cambridge, has been nominated by the President and Council of the Royal Society to be recommended for election by the Society on June 4, in place of the late T. R. Lewis, one of the selected candidates, who died soon after the selection was made.

SINCE our last week's note the eruption of Mount Etna has gone on increasing in violence. A correspondent of the *Standard* sends some valuable notes on the progress of the eruption. Under date Catania, May 19, 8.40 a.m., he writes :—"The eruption of Mount Etna assumed alarming proportions last evening at 5 o'clock. Earthquake shocks were felt in all the communes in the immediate vicinity of the volcano. At Zafferato, where the shocks appear to have been attended with upheaval of the soil, the disturbance is described as being so severe that the panic-stricken inhabitants fled from the neighbourhood. In the district of Bronte heavy showers of sand descended, and a gigantic column of thick black smoke was seen to emerge from the central crater of Etna towards the west." "10 a.m. An eruption has occurred near Nicolosi, to the north-west of Montegrosso, quite as severe in character as that of 1883. The lava has begun to stream down towards Nicolosi, accompanied by severe shocks of earthquake. 10.55 a.m. In addition to the

[1] Eichwald, "Ueber das Mucin besonders der Weinbergschnecke," *Annal. Chem. Pharm.*, cxxiv. 1865, pp. 177 to 211. Obolensky, "Ueber Mucin aus der Submaxillardrüse," Pflüger's *Archiv*, vol. iv. p. 336.

eruption which has taken place in Etna itself another one occurred about 2 a.m. in Prince of Naples Mount, situated about 9 kilometres north-east of Nicolosi. This is one of the 'red' mountains, formerly volcanic, but which has hitherto been regarded as exhausted. The lava is running in two streams towards the open country. Repeated and very severe shocks of earthquake are being felt in the vicinity of Etna. 11.55 a.m. A short time ago a severe shock of earthquake of an undulating kind was felt. The eruption of Prince of Naples Mount is increasing in severity. The lava is running rapidly in a double stream towards Nicolosi, to the great danger of the town. Panic amongst the inhabitants." "Nicolosi, May 19, noon. The eruption is assuming terrific proportions. The lava has advanced over 3 kilometres in 8 hours, continuing its course steadily towards Nicolosi. From the central crater, where the eruption is still very active, the lava is flowing towards Montegrosso." "Catania, May 19, 2 p.m. The eruption threatens the destruction of the western portion of the Etna forests. Last night several volcanic rents occurred between Nicolosi and Pedara. May 20. Eleven craters have been opened, of which three have assumed enormous proportions. The lava is advancing rapidly. In some places the stream is 200 metres broad. The central crater, however, emits only vapour and cinders." "Nicolosi, May 20. Three of the craters are raging fearfully, emitting huge stones to a considerable height, and the roar and tumult is terrible. The lava is advancing rapidly, but for the present it is uncertain what direction it may take, whether towards Nicolosi or Belpasso. Shocks of earthquake still continue, but they are less severe in character. The craters are situated behind Montezzano, in the valley between that place and Montenero. The people of the district assert that they can remember no eruption so sudden and alarming as this has been. The scene is indescribable. The streams of lava are in some places more than 200 metres in width. The central crater on the summit continues to vomit large columns of smoke; but from this, according to Prof. Silvestri, no danger is to be apprehended." "Acireale, May 20. Last evening, through the night, and this morning, many shocks of earthquake were felt at Piedimonte, Acisantangelo, Linguaglossa, and Acireale." "Catania, May 20. This morning, with a severe shock of earthquake, the volcanic orifice which was so active in 1883 was reopened." "Nicolosi, May 20. The activity of the central crater is increasing. Montegrosso is the principal site of eruptive force. Great alarm exists among the inhabitants, and the houses most likely to be in danger are being evacuated. The local authorities are on the spot." On Sunday the eruption had greatly diminished, but on Monday morning it broke forth with great violence, and a fresh crater sent out a stream of lava 150 metres wide and 23 deep towards Nicolosi. On Monday evening the news was very disquieting. The violence of the eruption was then greatly increasing, and Nicolosi seemed doomed to destruction. The noise at a considerable distance is described as resembling a continuous cannonade.

AT the meeting of the Paris Academy of Sciences on Monday, M. de Lesseps asked for the appointment of a committee to report on the alleged difference of sea-level on the two sides of the Isthmus of Panama. A similar objection to the Suez Canal had, he said, proved unfounded; and if the present objection were also disposed of, no locks would be necessary in the canal. On the motion of Admiral Jurien de la Gravière, who suggested that the tides might be higher on one side of the Isthmus than on the other, the question was referred to the navigation and astronomy sections. Meantime it is stated that the Technical Commission to whom M. de Lesseps had referred certain questions have affirmed unanimously that there is no insurmountable difficulty to the completion of the Canal according to the technical programme adopted by the Company—that is to say, that there will be no necessity to construct the Canal with locks, the level of the two oceans being the same.

THE committee for the celebration of the centenary of Arago will issue shortly an appeal for subscriptions to erect a statue to the celebrated astronomer on the Place St. Jacques. A new boulevard will be opened in the direction of the meridian for connecting Paris and Montsouris Observatories.

A COUNTY Scientific Society for Middlesex has been constituted, to which both ladies and gentlemen are eligible. The Right Hon. Viscount Enfield, Lord-Lieutenant of the county, has consented to be the President of the Society; and the Right Hon. the Earl of Crawford and Balcarrēs, the Right Hon. the Earl of Aberdeen, the Right Hon. the Marquis of Ripon, Prof. T. H. Huxley, Sir John Lubbock, Prof. W. H. Flower, Sir Frederick Abel, and Dr. Archibald Geikie having intimated to the Provisional Committee their approval of the scheme and their readiness to become Vice-Presidents of the Society, were at the meeting constituting the Society elected to this office. The following gentlemen were elected members of the Council of the Society, the list to be subsequently increased:—W. Lant Carpenter, Herbert Druce, J. N. Dunning, E. Fitch, G. Griffiths, R. B. Hayward, J. Logan Lobley, Rev. Dr. C. McDowall, Wm. Simpson, Rev. Dr. F. A. Walker, Rev. J. Crane Wharton, W. Mattieu Williams. It is intended that the Society shall hold monthly meetings (evening) from about October to May, and field-meetings during the summer months. Names of ladies or gentlemen desirous of joining may be sent to the Hon. Secretary, Mr. Sydney T. Klein, Clarence Lodge, Church Road, Willesden, N.W.

THE eleventh public annual meeting of the Sunday Society was held on May 22. Sir Henry E. Roscoe, M.P., F.R.S., took the chair as President for the year. Mr. Mark H. Judge read the annual statement, pointing out the progress that had been made during the year in accomplishing the objects which the Society has in view. Sir Henry Roscoe, in his Presidential Address, quoted copiously from the utterances of past Presidents and of eminent men in all departments on behalf of the opening of museums, art galleries, and similar institutions on Sunday. Having had the honour, Sir Henry said, to serve on the Royal Commission on Technical Instruction, he had had full opportunity of observing the effects of the Sunday opening of the numerous museums, industrial, artistic, and scientific, which exist in Continental countries, and he stated that after such observations the unanimous conclusion to which the Commissioners arrived was that the influence which the opening of these museums on Sunday exerted, not only upon the industrial progress of those countries, but upon the moral and intellectual condition of their peoples, had been in the highest degree satisfactory. And so forcible was the evidence on this head then brought before them, that the Commissioners placed a distinct recommendation at the close of their Report, to the effect that museums of art and science and technological collections in this country should be opened to the public on Sundays. They point out in their Report that, in respect to museums, the people of this country stand in a position of great disadvantage as compared with Continental nations, and that to the influence of these collections, as regards the direct bearing they have on art and industrial training, is due much of the abundance of art resource so advantageous to many Continental industries and manufactures. Almost all these Continental art galleries and museums are opened to the public freely on Sundays, and Sir Henry had yet to learn that opposition has been anywhere raised to this, or that any objectionable features have there been introduced. Sunday opening in the United Kingdom, so far as it has gone—and that is a long way—has had an effect the reverse of that

anticipated by its opponents: museums, galleries, and libraries have been open on Sundays in thirteen towns for some years, with such success that the only opposition in those towns is one which does not show itself in public. The town of Oldham is now trying the experiment of Sunday opening for four Sundays, to-morrow being the second Sunday; and Sir Henry had a letter from the Mayor of that important northern town, stating that on last Sunday crowds of well-behaved persons passed through the gallery, and that he is satisfied of the importance and good influence of the movement. Sir Henry concluded:—"We challenge the Sabbatarian party to be true to their own opinions, as we are to ours. We ask for more of what we say has been a blessing. They refuse their assent on the plea that Sunday opening *per se* is a curse. They show by their actions that they are only half believers in their own statements. We challenge them to take a vote on the direct question as to whether those museums and galleries now open should remain open or not." The meeting authorised the Committee of the Society to send a memorial to H.R.H. the Prince of Wales, requesting that in the interest of the community the Colonial and Indian Exhibition should be opened on a few Sundays by free tickets.

MR. EDGAR CROOKSHANK writes, with reference to our article on the Royal Society *soirée* last week, to say that by a slip the exhibition of micro-photographs and preparations of Bacteria were assigned to his friend Mr. Cheshire. The collection of photographs was exhibited by request, and represent many months' work in endeavouring to overcome the difficulties of obtaining satisfactory results with the use of high powers (1-25th, 1-18th, and 1-12th, o.i.). In many cases of preparations of Bacteria, such as *cover-glass preparations*, and especially the so-called *impression-preparations*, and particularly where there is much detail, Mr. Crookshank maintains that photography is the only satisfactory means for obtaining an accurate picture. In such cases photography excels in affording us absolute faithfulness.

THE hybrid trout reared at the South Kensington Aquarium from the ova of the sea-trout, *S. trutta*, impregnated with the milt of the common trout, *S. fario*, in December last, show unmistakable signs of hardihood. Comment has been made previously in this journal upon the subject, as the facts adduced evidence the capacity of Salmonidæ to give ova without descending to the sea. There has been a much less percentage of mortality not only amongst the ova but the fry. At the present time they are located in a special pond at the Delaford Park Fishery belonging to the National Fish Culture Association, where they continue to thrive exceedingly well. They were encouraged to feed after losing their sac sooner than other species of fry; and without exception are growing rapidly.

ON Saturday last 12,000 Severn salmon fry were turned into the River Dee. The ova were spawned by the Severn Fishery Board, and hatched out by the National Fish Culture Association. A large number of the same species will be deposited this week in the Severn, having been reared at South Kensington for this purpose.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Capt. Boyle; two Squirrel Monkeys (*Chrysothrix sciurea*) from Brazil, presented by Mr. George Liddell; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Mrs. F. E. A. Prince; three Speckled Terrapins (*Clemmys guttata*), seven Painted Terrapins (*Clemmys picta*), a Sculptured Terrapin (*Clemmys insculpta*), eleven Striped Snakes (*Tropidonotus sirtalis*), three Ribbon Snakes (*Tropidonotus saurita*), seven Dekays Snakes (*Ischnognathus dekayi*), four Grass Snakes (*Cyclophis vernalis*) from North America, presented by Mr. Samuel Garman, C.M.Z.S.; three Spanish Terrapins (*Clemmys leprosa*), European, presented by Mr. Cuthbert Johnson; a Quail (*Coturnix communis*), European, presented by Mr. Kenneth Lawson; four Menobranchs (*Menobranchus lateralis*) from North America, presented by Prof. Ramsay Wright; two Wild Ducks (*Anas boschas*), British, presented by Mr. G. Edison; a Common Viper (*Vipera berus*), British, presented by Mr. Percy E. Coombe; a Macaque Monkey (*Macacus cynomolgus*) from India, deposited; two Spotted Hyænas (*Hyæna crocuta*) from South Africa, two Ruffs (*Machetes pugnax*), three Viperine Snakes (*Tropidonotus viperinus*), European, two Lion Marmosets (*Midas rosalia*), a Spotted Cavy (*Cœlogenys paca*), two Ariel Toucans (*Ramphastos ariel*), two Crested Curassows (*Crax alector*), a Zenaida Dove (*Zenaida amabilis*) from Brazil, purchased; four Bernicle Geese (*Bernicla leucopsis*), European, received in exchange; a Gayal (*Bibos frontalis*), an African Wild Ass (*Equus tæniopus*), a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE HELIOMETER OF THE YALE COLLEGE OBSERVATORY.—From Dr. Elkin's report of the work done during the year ending June 1, 1885, we learn that the principal object of research has been the triangulation of the Pleiades, to which work the heliometer was devoted from September 1884 to March 1885. It was originally intended to confine the investigation to the stars measured at Königsberg and to carry out only one method of triangulation. The scheme has been extended, however, to include all the stars in the Bonn *Durchmusterung*, within certain limits, down to magnitude 9·2, making sixty-nine stars in all, and also to obtain a determination of the relative positions of the stars which should be strictly comparable with the Königsberg work, viz. measurement of distances and angles of position of the stars from Alcyone. The observations have all been reduced provisionally; the final reduction cannot be undertaken until the results of the meridian observations of the end stars of two zones serving to determine the scale value and zero of position have been received from the observatories which have consented to make them. Measures of the moon from neighbouring stars have also been made on thirty-six nights near the first and last quarters, and the diameter of the moon has been measured at opposition on seven occasions. Observations have also been made of the diameter of Venus, the outer ring of Saturn, and of Titan referred to its primary. It is now proposed to devote the heliometer to systematic investigations in stellar parallax, and, judging from the results which have been obtained by Gill and Elkin at the Cape, we may expect that most valuable work will be done in this direction with the heliometer at Yale College also.

ECLIPSE OF JUPITER'S FOURTH SATELLITE.—Mr. Marth pointed out some two years ago, in a paper read before the Royal Astronomical Society (*Monthly Notices*, vol. xliv. p. 241), the importance of observing those eclipses of the fourth satellite of Jupiter which commence or end a series, in order to obtain data for correcting the tables. A slight error in latitude shows itself very strikingly on such occasions in the duration of the eclipse. Such observations are unfortunately very rare, the Greenwich eclipse observations from 1836 to 1883 not affording a single instance of an observation which will assist in correcting the latitude. Mr. John Tebbutt, Windsor, New South Wales, noticing that two of the last eclipses of the cycle just closed were visible in New South Wales, drew attention to these facts in the *Sydney Morning Herald* for March 27. We learn from a communication in the number for April 1 of the same paper that Mr. Tebbutt was successful in his own observations of the phenomenon. The disappearance of the satellite took place at 14h. 38m. 34s. Windsor mean time, or 15m. 43s. *before* the time given in the *Nautical Almanac*. The reappearance, on the contrary, was 8m. 55s. *late*, the duration thus being 24½m. longer than the predicted time. Mr. Russell, at Sydney, noted that the satellite had already disappeared when he began to observe, quite six minutes before Mr. Tebbutt lost sight of it. Mr. Tebbutt was convinced, however, of the accuracy of his now observation.

A NEW COMET.—Mr. W. H. Brooks, Red House Observatory, Phelps, New York, discovered a bright comet on May 23, 15h. Greenwich mean time. Its position was as follows:—R.A. 11h. 55m., Decl. 8° 55′ N.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *MAY* 30—*JUNE* 5

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 30

Sun rises, 3h. 52m.; souths, 11h. 57m. 15·7s.; sets, 20h. 2m.; decl. on meridian, 21° 48′ N.: Sidereal Time at Sunset, 12h. 35m.

Moon (New on June 2) rises, 2h. 37m.; souths, 9h. 20m.; sets, 16h. 14m.; decl. on meridian, 7° 36′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′

GEOGRAPHICAL NOTES

In his presidential address at the annual meeting of the Royal Geographical Society on Monday, the Marquis of Lorne, referring to the matter of geographical education, said that the interest excited in the subject by the Society's recent action has been so great, and the expectation that the Society will continue it by taking some positive steps towards encouraging improvements in the position of geography in schools and Universities is so general, that the Council have felt encouraged and indeed bound to carry the scheme further. The Educational Committee of the Society therefore made certain suggestions to the Council, which are now under consideration, and will probably be adopted. The principal of these suggestions relates to the appointment of a lecturer in geography to deliver courses where the Council may direct. In this matter the Council will take suitable steps to obtain the co-operation of the Universities of Oxford and Cambridge. In order still further to encourage the scientific study of geography at the Universities, the Committee suggest that a prize or travelling scholarship be given every alternate year to a student who has shown marked ability in geographical subjects, and who may desire to visit one of the less-known districts of Europe, or the Mediterranean or Black Sea shores, and any results be communicated to the Society. One or other of the annual grants which are at the Society's disposal might be devoted to this purpose. Another suggestion is aimed at reaching the intelligent middle and working classes through the medium of the University Extension Scheme. For this purpose a small annual grant is proposed. Another is that a medal be given by the Society to the student reported by the examiners to have done best in physical geography in the first part of the Natural Sciences Tripos (Honours Examination). And finally, in order that all classes of schools may be reached, it is proposed that prizes be offered for competence in geography to the students at the various training-colleges. "Here we reach the fountain-head of education, and if we can secure adequate attention to geography in the institutions which send forth yearly troops of teachers to our Board and elementary schools, the Society will have accomplished much. It is evident, then, that the Society has already accomplished a great deal. The mind of the public has been aroused and greatly enlightened on the subject; our best schools and Universities have expressed their willingness to co-operate as far as possible in carrying out improvements; and there can be little doubt that our proposed further action will bring results which the Council and all interested in geography have long desired."

In a paper contributed to the *Bulletin* of the Moscow Society of Naturalists (1885, No. 2) M. Smirnoff continues his most valuable delimitation of the vegetable zones of the Caucasus, which forms an introduction to a flora of the vascular plants of the region. He subdivides Transcaucasia into several zones, the central zone extending east to the meridian of Shemakha. This limit does not correspond to any orographical features, but separates from the remainder of Transcaucasia the region subject to the influence of the Caspian Sea. The littoral of the Black Sea in Transcaucasia is distinguished from the rest of the region by high winter temperatures. As far as lat. 44° N., and even at an altitude of 150 metres, the winter is as mild as in Provence or in Central Italy, only the setting in of warm weather in spring being a little later. But as soon as the chain is crossed we find a rapid decrease of the winter temperature, so that Yekaterinodar, on the northern slope of the chain, although only 20 miles further to the north and 1° of longitude more to the east than Novorossiysk, has an average temperature during December and January 4° lower. Baku and Lencoran have winters very much like those of the Venetian littoral, but Derbent shows a sudden decrease of 3°·5 of temperature in January, probably due to the influence of ice gathering in the northern part of the Caspian Sea, while Petrovsk, only 70 miles further north on the same coast, shows a further sudden decrease of temperature in January. The ranges of the monthly average temperatures of different places show a still greater difference of climate. Thus, on the Black Sea coast, south of lat. 44° N., and even at Kutais, the difference between the warmest and the coldest months does not exceed 18° to 19°; it is the same as at Trieste and Athens. But in Ciscaucasia it reaches 25°, and on the Caspian littoral it varies from 22°·4 at Baku to 29°·8 at Petrovsk. It is still greater on the Armenian plateau (30° to 35°); while in Central Transcaucasia it is generally less than 25°, and rapidly diminishes with the altitude of the place, reaching no more than 19°·5 at Shusha. These few data, together with a map of isotherms prepared by M. Smirnoff, give a broad general idea as to the climatic conditions of the Caucasus, and the consequent distribution of different regions of vegetation through the country.

TELESCOPIC OBJECTIVES AND MIRRORS: THEIR PREPARATION AND TESTING [1]

It would probably lend an additional interest to a technical subject such as I have to bring before you to-night, could I preface my description of the processes now employed in the

[1] Lecture given at the Royal Institution on Friday, April 2, 1886, by Mr. Howard Grubb, F.R.S., F.R.A.S.

construction of telescopic objectives by a short historical account of what has been attempted and achieved in the past, but time will not permit.

A very few words, however, on the history of glass manufacture are necessary.

As I pointed out last Saturday afternoon, Dollond's brilliant discovery, which afforded a means of achromatising objectives, rendered possible their construction of greater size and perfection than formerly, provided suitable material could be obtained. But the chromatic errors being removed, faults in the material hitherto masked by them were detected, and it was not until after many years that Guinand, a lowly but gifted Swiss peasant, succeeded in producing glass disks of a considerable size and free from these defects.

The secrets of his process have been handed down in his own family to M. Feil, of Paris (one of his descendants), and also through M. Bontemps, who for a time was associated with Guinand's son, and afterwards accepted an invitation from Messrs. Chance Bros. and Co., of Birmingham, to assist them in an endeavour to improve that branch of their manufacture. Only these two houses, so far as I am aware, have succeeded in manufacturing optical disks of large size.

Testing of Optical Glass.—Let me here say a few words respecting the testing of optical glass; I mean of the material of the glass, quite apart from the optician's work in forming it into an objective. When received from the glass manufacturer it is sometimes in this state, roughly polished on both sides, and sometimes in this, in which as you see there are small windows only, facets as they are called, polished on the edges. In case of lenses for telescopic objectives, it is always well to have them roughly polished on the sides, to avoid the chance of having to throw away a lens after much trouble and labour has been spent on it.

There are only three distinct points to be looked to in the testing of optical glass: (1) general clearness and freedom from air-bubbles, specks, pieces of "dead metal," &c.; (2) homogeneity; (3) annealing.

The first is the least important, and needs no instructions for detection of defects, any one can see these. The second is much more important, and much more difficult to test.

The best test for homogeneity is one somewhat equivalent to Foucault's test for figure of concave mirrors.

The disk of glass should be either ground and polished to form a convex lens, or if that be not convenient, it should be placed in juxtaposition with a convex lens of similar or larger size, and whose excellence has been established by previous experience.

The lens or disk is then placed opposite some small brilliant light, a small gas flame generally suffices, and at such a distance that a conjugate focus is formed at other side and at a convenient distance. When the exact position of this focus is found, the eye is placed as nearly as possible so that the image of flame is formed on the pupil. On looking at it with the eye in this position, the whole lens should appear to be "full of light"; but at the slightest movement to one side the light will disappear and the lens appear quite dark. If the eye be now passed slowly backwards and forwards between the position showing light and darkness, any irregularity of density will be most easily seen.

Of course, like everything else, some experience is necessary.

The rationale of this is very obvious. When the eye is placed exactly at the focus of a perfect lens, the image formed on the pupil is very small, and the slightest movement of the eye will cause the light to appear and disappear. If the eye be not at the focus, the pencil of light will be larger, and consequently it will require a much greater movement of the eye to cause the light to disappear. Now if any portion of the lens be of a different density to the general mass, that portion will have a longer or a shorter focus; consequently while the light flashes off the general area of the lens quickly, it still remains on the defective portions.

By imitating this arrangement and substituting a camera for the eye and forming the focus of a small point of light on the stop of the lens, I have succeeded in photographing veins in glass, and sometimes have found this useful as a record.

The third point—that of proper annealing—is easily tested by the polariscope.

For small disks the usual plan is to hold them between the eye and a polarising plane, such as a piece of glass blackened at back or a japanned surface, and look at them through the facets, using as an analyser a Nicol prism.

Larger sizes, which are polished on the surfaces, can be more easily examined. It is difficult to describe the appearances, but I will put a few disks into the lantern polariscope and endeavour to point out what amount of polarisation may safely be permitted in disks of glass to be used for objectives.

The composition of metallic mirrors of the present day differs very little from that used by Sir Isaac Newton. Many and different alloys have been suggested, some including silver or nickel or arsenic; but there is little doubt that the best alloy, taking all things into account, is made with 4 atoms of copper, and 1 of tin, which gives the following proportions by weight: copper, 252, tin, 117·8.

Calculation of Curves.—Having now obtained the proper material to work upon, the first thing necessary is to calculate the curves to give to the lenses, in order that the objective, when finished, may be of the required focus, and be properly corrected for the chromatic and spherical aberrations.

As this lecture is intended to deal principally with the technical details of the process, I do not intend to occupy your time for more than a few moments on this head, nor indeed is it at all necessary. In my lecture last Saturday I explained the principles of achromatism, and in many published works full and complete particulars are given as to the calculation of the curves—particulars which are sufficient, and more than sufficient, for the purpose.

Much has been discussed and written concerning the calculation of curves of objectives, and much care and thought has been bestowed by mathematicians on this subject, and, so far as the actual constructors are concerned, a certain amount of veil is thrown over this part of the undertaking, as if there were a secret involved, and as if each had discovered some wonderful formulæ by which he was enabled to calculate the curves much more accurately than others.

I am sorry to have to dispel this illusion. Practically the case stands thus. The calculation of the curves which satisfy the conditions of achromatism and desired focus is a most simple one, and can be performed by any one having a very slight algebraical knowledge in a few minutes, provided the refractive indices and dispersive power of the glass be known. Both Messrs. Chance and Feil supply these data quite sufficiently accurately for small size objectives. Speaking for myself, I am quite content to take the figures as given by these glass manufacturers for any disk up to 10 inches in diameter. If over that size, I grind and polish facets on the disk and measure the refractive and dispersive powers myself.

The calculations of the curves required to satisfy the conditions of spherical aberration are very troublesome, but fortunately these may be generally neglected.

Some years ago the Royal Society commissioned one of its members to draw up tables for the use of opticians, giving the curves required to satisfy the conditions of both corrections for all refractive and dispersive indices.

A considerable amount of labour was expended on this work, but in the end it was abandoned, for it was found that the calculation of these curves was founded on the supposition that all surfaces produced by the opticians were truly spherical; while the fact is, a truly spherical curve is the exception, not the rule. The slightest variation in the form or figure of the curve will produce an enormous variation in the correction for spherical aberration, and it was soon apparent that the final correction for spherical aberration must be left to the optician and not to the mathematician. *Object-glasses cannot be made on paper.* When I tell you that a sensible difference in correction for spherical aberration can be made by half an hour's polishing, corresponding probably to a difference in the first place of decimals in radii of the curves, you will see that it is practically not necessary to enter upon any calculation for spherical aberration. We know about what form gives an approximate correction; we adhere nearly to that, and the rest is done by figuring of the surface.

To illustrate what I mean. I would be quite willing to undertake to alter the curves of the crown or flint lens of any of my objectives by a very large quantity, increasing one and decreasing the other so as to still satisfy the conditions of achromatism, but introducing theoretically a large amount of positive or negative spherical aberration, and yet to make out of the altered lens an object-glass perfectly corrected for spherical aberration.

I am now speaking of ordinary sizes. For very large sizes it is usual to go more closely into the calculations; but I may

remark that it is sometimes possible to make a better objective by deviating from the curves which give a true correction for spherical aberration and correcting that aberration by figuring, rather than if the strictly theoretical curves were adhered to. So far, then, as any calculation is required, the ordinary formulæ given in the text-books may be considered amply sufficient.

Having now determined on the curves, we have to consider the various processes which the glass has to undergo from the time it is received in this form from the glass manufacturer to the time when it is turned out a finished objective.

The work divides itself into five distinct operations: (1) rough grinding; (2) fine grinding; (3) polishing; (4) centering; (5) figuring and testing.

(1) The rough grinding or approximate shaping of the glass is a very simple process. The glass is cemented on a holder, and is held against a revolving tool supplied with sand and water, and of a shape which will tend to abrade whatever portions are necessary to be removed to produce the required curves. These diagrams will illustrate the various operations.

(2) Fine grinding. The tools used for fine grinding are of this form, and are made of either brass or cast iron. I prefer cast iron, except for very small sizes. They are grooved on the face, in the manner suggested by the late Mr. A. Ross, in order to allow the grinding material to properly distribute itself.

If two spherical surfaces be rubbed together they will, as may be supposed, tend to keep spherical; for the spherical is the only curve which is the same radius every part of its surface. If fine dry abrading powder be used between, the same result will be obtained; but, if wet powder be used, the surface will no longer continue spherical, but will abrade away more on the centre and edge than in the zone between. It was to meet this difficulty that the late Mr. A. Ross devised the idea of the distributing grooves. The fine grinding process is the first of the series which calls for any skill on the part of the operator.

That the *modus operandi* of the grinding be the more easily understood, let me explain the principle of the process in a few words.

When two surfaces of unequal hardness are rubbed together with emery powder and water between the two, each little particle of the powder is at any given moment in either of these conditions: (*a*) embedded into the softer surface; (*b*) rolling between the two surfaces; (*c*) sliding between the two surfaces.

Those particles which become embedded in the softer material do no work in abrading it, and but little in abrading the harder. They generally consist of the finer particles, and are kept out of action by the coarser which are rolling or sliding between the surfaces. Further, those that are purely rolling do little or no work. The greater part of the work is performed by those particles which are facetted and which *slide* between the two surfaces.

As the grinder is always of a much softer material than the glass, there is much more friction between the grinder and these particles than between the glass and the same particles, and therefore they partially adhere to the grinder and are carried by it across the face of the glass. This being so, it is now easy to perceive what the best conditions for rapid grinding are. Not too little emery, for then there will not be enough of abrading particles; not too much, for then the particles will roll on each other and tend to crush and disintegrate each other instead of abrading the glass, but just sufficient to form a single layer of particles between the grinder and the glass surface.

In the grinding of the small lenses, I mean up to 5 or 6 inches diameter, it is usual to carry out the entire grinding processes by hand; above that size by machinery. Surfaces up to 12 or even 15 inches can be ground by hand; but the labour becomes severe, and for my part I am gradually reducing the size for which the hand grinding is used, as I find the machine work more constant in its effects.

The machinery used is the same as that employed for the polishing operation, and I shall describe it under that head further on.

In the fine grinding operation by hand, the glass is usually cemented on to a holder of this form, having (for smaller sizes) three pieces of cork, to which the lens is attached, and this holder being screwed to a spud or nose on top of a post screwed to the floor. The operator, having applied the proper quantity of moist emery powder between the grinder and the glass, proceeds to work the former over the latter in a set of peculiar strokes, the amplitude and character of which he varies according to circumstances, at the same time that he changes his position round the post every few seconds. . . .

Although, as I have shown, the harder material is abraded very much more than the softer, yet the softer (the grinder) suffers considerable abrasion as well as the glass, and the skill of the operator is shown by the facility with which he is able to bring the glass to the curve of the grinder without altering the curve or figure of the latter.

It is even possible for a skilled operator to take a lens of one curve and a grinder of, say, a deeper curve, and by manipulation to produce a pair of surfaces fitting together, and of shallower curves than either.

Measurement of the Curves.—In the early stages of grinding, gauges of the proper radius, cut out of sheet brass or sheet steel, are used for roughly testing the curves of the lenses; but when we get to the finer grinding process it is necessary to have something much more accurate.

For this purpose a spherometer is used. It is made in various forms, generally with three legs terminating in three hardened steel points, which lie on the glass, and a central screw with fine thread, the point of which can be brought down to bear on the centre of the glass. In this way the versed sine of the curve for a chord equal to diameter of circle formed by these points is measured, and the radius of curve can be easily calculated from this.

I do not find the points satisfactory for regular work. They are apt to get injured or worn, and for ground surfaces are a little uncertain, as one or other of the feet may find its way into a deep pit. This particular spherometer has three feet, of about half an inch long, which are hardened steel knife-edges forming three portions of an entire circle. In using this it is laid on the surface to be measured, and the screw with micrometer head is turned till the point is felt to touch the surface of glass. This scale and head can then be read off. The screw in this instrument has fifty threads to the inch, and the head is divided into 100 parts, so that each division is equal to $\frac{1}{5000}$ of an inch. With a little practice it is easy to get determinate measures to $\frac{1}{10}$ of this, or $\frac{1}{50000}$ of an inch, and by adopting special precautions even more delicate measures can be taken, as far probably as $\frac{1}{100000}$ or $\frac{1}{150000}$ of an inch, which I have found to be practically the limit of accuracy of mechanical contact.

To give an idea of the delicacy of the instrument, I bring the screw firstly into contact with the glass. Now the screw is in good contact; but there is so much weight still on the three feet, that, if I attempt to turn it round, the friction on the feet oppose me, and it will not stir except I apply such force as will cause the whole instrument to slide bodily on the glass. Now, however, I raise the whole instrument, taking care that my hands touch none of the metal-work, and that the screw be not disturbed. I lay my hands for a moment on part of the glass where centre screw stood, and thus raise its temperature slightly, and on laying the spherometer back in the same place, you now see that it spins on the centre screw, showing how easily it detects what to it is a large lump, caused by expansion of the glass from the momentary contact of my hand.

Flexure.—One of the greatest difficulties to be contended with in the polishing of large lenses is that of flexure during the process.

It may appear strange that in disks of glass of such considerable thickness as are used for objectives, any such difficulty should occur; but a simple experiment will demonstrate the ease with which such pieces of glass can be bent, even under such slight strain as their own weight.

We again take our spherometer and set it upon a polished surface of a disk of glass of about $7\frac{1}{2}$ inches diameter and $\frac{3}{4}$ inch thick. I set the micrometer head as in the former experiment to bear on the glass, but not sufficiently tight to allow the instrument to spin round. This has now been done while the glass, as you see, is supported on three blocks near its periphery. I now place one block under the centre of disk and remove the others thus, and you see the instrument now spins round on centre screw.

It is thus evident that not only is this strong plate of glass bending under its own weight, but it is bending a quantity easily measurable by this instrument, which, as I shall presently show, is quite too coarse to measure such quantities as we have to deal with in figuring objectives.

After this experiment no surprise will be felt when I say that it is necessary to take very special precautions in the supporting of disks during the process of polishing, to prevent danger of

flexure; of course if the disks are polished while in a state of flexure, the resulting surface will not be true when the cause of flexure is removed.

For small-sized lenses no very special precautions are necessary, but for all sizes over 4 inches in diameter I use the equilibrated levers devised by my father, and utilised for the first time on a large scale in supporting the 6-foot mirror of Lord Rosse's telescope. These have been elsewhere frequently described, but I have a small set here as an example.

I have also sometimes polished lenses while floating on mercury. This gives a very beautiful support, but it is not so convenient, as it is difficult to keep the disk sufficiently steady while the polishing operation is in progress without introducing other chances of strain.

So far I have spoken of strain or flexure during the process of working the surface; but even if the surface be finished absolutely perfectly, it is evident from the experiment I showed you that very large lenses when placed in their cells must suffer considerable flexure from their own weight alone, as they cannot then be supported anywhere except round the edge.

To meet this I proposed many years ago to have the means of hermetically sealing the tube, and introducing air at slight pressure to form an elastic support for the objective, the pressure to be regulated by an automatic arrangement according to the altitude. My attention was directed to this matter very pointedly a few years ago from being obliged to use for the Vienna 27-inch objective a crown lens which was, according to ordinary rules, much too thin.

I had waited some years for this disk, and none thicker could be obtained at the time. This disk was very pure and homogeneous, but so thin that, if offered to me in the first instance, I would certainly have rejected it. Great care was taken to avoid flexure in the working, but, to my great surprise, I found no difficulty whatever with it in this respect. This led me to investigate the matter, with the following curious results.

If we call f the flexure for any given thickness t, and f' the flexure for any other thickness t', then $\frac{f}{f'} = \frac{t'^2}{t^2}$ for any given load or weight approximately. But as the weight increases directly as the thickness, the flexure of the disks due to their own weight, which is what we want to know, may be expressed as $\frac{f}{f'} = \frac{t'}{t}$.

Let us now consider the effect of this flexure on the image. In any lens bent by its own weight, whatever part of its surface is made more or less convex or concave by the bending has a corresponding part bent in the opposite direction on the other surface, which tends to correct the error produced by the first surface. This is one reason why reflectors which have not this second correcting surface are so much more liable to show strain than refractors. If the lens were infinitely thin, moderate flexure would have no effect on the image. The effect increases directly as the thickness. If then the flexure, as I have shown, decreases directly as the thickness, and the effect of that flexure increases directly as the thickness, it is clear that the effect of flexure of any lens due to its own weight will be the same for all thicknesses; in other words no advantage is gained by additional thickness.

This has reference, of course, only to flexure of the lens in its cell after it has been duly perfected, and has nothing to do with the extra difficulty of supporting a thin lens during the grinding and polishing processes.

Polishing.—The polishing process can be, and is often, conducted precisely in the same manner as the grinding, except that the abrading powders used (oxide of iron, rouge, an oxide of tin, putty-powder) is of a finer and softer description, and the surface of the polishing tool is made of a softer material than the metallic grinder.

Very nearly all my polishing is done on the machine I shall presently describe; but before doing so, I will, with your permission, say a few words on the general principles of the polishing process. Various substances are used for the face of the polisher—fine cloth, satin or paper, and pitch. Pitch possesses two important qualities which render it peculiarly suitable for this work, and it is a curious fact that we owe its application for this purpose to the extraordinary perspicuity of Sir Isaac Newton, who we may fairly say was the first to produce an optically perfect surface, and that that material is not only still used for the purpose, but is, as far as I know, the only substance which possesses the peculiar qualifications necessary to fulfil the required conditions. With skill and care, moderately good surfaces can be obtained from cloth polishers; but it is easy to see why they can never be perfect. There is a certain amount of elasticity in cloth and in its "nap," and there is consequently a tendency to round off the surfaces of the pits left by the grinding powder, and to polish the bottom or floor of these pits at the same time as the upper surface. It is easy to show mathematically that any process which abrades the floors of the pits at the same time as general surfaces even in a very much less degree, can never produce more than an approximation to a perfect surface, and practice agrees with the theory. Paper is said to be much used by the French opticians. I can say nothing about it. I have tried it and failed to produce a perfect surface with it, nor indeed should I expect it. It is of course open to the same objection as cloth. Pitch possesses, as I said, two most important qualities which render it suitable for the work; the first, in its almost perfect inelasticity; the second, a curious quality of subsidence, which we utilise in the process.

If we watch with a microscope, or even a magnifier, the character of two surfaces during the process of polishing, the one with cloth, and the other with pitch, the difference is very striking. With the cloth polisher, the polish appears much quicker, and it would at first sight appear as if the same polishing powder abraded more quickly on the cloth than on the pitch polisher, but I do not believe that such is the case, for if we look at the surface with a magnifier we shall find that, while all the surface has assumed a polished appearance, the surface itself has retained some of the form of the original pitted character with the edges rounded off; while in the pitch half-polished surfaces the floors of the pits are as gray as ever, and the edges are sharp and decisive. In pitch polishing, too, a decided amount of polish appears very quickly, and then for many hours there appears to be little or no further effect. Suddenly, however, the remaining grayness disappears, and the surface is polished. The reason of this is very obvious. The polisher being very inelastic, polishes first only the tops of the hills, and has to abrade away all the material of which these hills are composed before it reaches the valleys or floors of the pits. When it does reach them, the proper polish quickly appears. The second quality of pitch, that of subsidence, is also most valuable.

Pitch can be rendered very hard by continued boiling. By pitch I mean the natural bituminous deposit which comes to us from Archangel, not gas-tar pitch. It can be made so hard that it is impossible to make any impression on it with the finger-nail without splitting it into pieces; and yet even in this hard condition, if laid on an uneven surface it will in a few days, weeks, or months subside and take the form of whatever it is resting upon. The cohesion of its particles is not sufficient to enable it to retain its form under the action of gravity; and as this condition is that which science tells us marks the difference between solids and liquids, we must, paradoxical though it may appear, class even the hardest pitch among liquid instead of solid substances.

Now how do we utilise this peculiar quality?

The polishing tool is made by overlaying a metal or wooden disk formed to nearly the required curves by a set of squares of pitch, and while these are still warm pressing them against the glass, the form of which they immediately take.

In the grinding process I showed you that the regulation of the abrasion was managed partly by the character of the stroke given, and partly by the local touches given to the tool by the stoning process.

In polishing we still retain the same facilities for modifying the stroke, and the same rules I gave apply generally to the polishing process as well as the grinding; but we have not got any process equivalent to that of the local stoning, and even if we had it would be useless, for this very quality of subsidence of the pitch would in a few minutes cause any part of its surface which had been reduced to come into good contact again; we must therefore look for some other means for producing more or less abrasion whenever we require it. This we effect by modifying the size of the squares of pitch in the various zones. Practically it is done in this way by a knife and mallet. Whenever the squares are reduced, the abrasion will be less.

This is a well-known method of regulation; but the rationale is, I think, not generally understood. It is generally explained that there is less abrasion because there is less abrading surface. I do not think this is the true, or at least the entire, explanation. In order to understand the action, you must conceive the pitch to be constantly in a state of subsidence, the amount of that

subsidence depending of course on the pressure placed upon it. Now, if we reduce the size of the squares in any zone while retaining the same distance from centre to centre of squares, we increase at first the pressure per unit of area on the pitch squares in that zone, and consequently the subsidence will be greater, and the action will not be so tight or severe on that zone.

I know of no substance but pitch and a few of the resins which possesses this peculiar quality except perhaps ice, and it is curious to think that the same quality which in ice allows of that gradual creeping and subsidence and consequent formation of glaciers with their characteristic moraines, &c., will in pitch help us to produce accurate optical surfaces.

Polishing-Machines.—The two best-known polishing-machines are those of the late Earl of Rosse and the late Mr. Lassell, the general forms of which were shown in these diagrams. Time will not permit me to enter into a minute description of their working, nor is it necessary, as both have been often described.

A few words, however, as to the different character of the strokes given by these machines may be interesting. The stroke of Lord Rosse's machine may be imitated in hand-work by the operator traversing the polisher or mirror in a series of nearly straight strokes, of about one-third the diameter of the glass, to and from himself, at the same time that he keeps walking slowly round the post, and instead of allowing the centre of polisher to pass directly over the centre of mirror, each stroke that he gives he slides a little (about one-tenth diameter) to one side and then a little to the other.

Mr. Lassell's stroke may be imitated by causing the polisher to describe a series of nearly circular strokes a little out of the centre, walking round the post at the same time; thus the centre of polisher will describe a series of epicycloidal or hypocycloidal curves on the speculum.

Many years ago my father devised a machine, figured and described in Nichols's "Physical Science," by which either of these motions could be obtained. He appeared to have got better results with Mr. Lassell's strokes, for he afterwards devised a machine which gave the same character of stroke, but over which the operator had greater control, and this machine has been used for many years with great success. Like all machines, however, which give a series of strokes constantly recurring of the same amplitude, it is apt to polish in rings It is impossible to obtain absolute homogeneity in the pitch patches, and if any one square be a shade harder than the general number, and that square ends its journey at each stroke at the same distance from the centre of speculum or glass, there will almost surely be a change of curvature in that zone. To avoid this I have made a slight modification in the machine, which has increased its efficiency to a great extent. I will now place in the lantern a model of this machine, and first draw you a few curves with the machine in its old state, and afterwards in its improved state.

In order to convey some idea of the relative quantities of material removed by the various processes, I have placed upon the walls a diagram which will illustrate this point in two distinct ways.

The diagram itself represents a section of a lens of about 8 inches aperture and 1 inch thick, magnified 100 times, and shows the relative thickness of material abraded by the four processes.

The quantity removed by the rough grinding process is represented on this diagram by a band 25 inches wide, the fine grinding by one $\frac{8}{10}$ inch wide, the polishing by a line $\frac{1}{50}$ inch wide, while the quantity removed by the figuring process cannot be shown even on this scale, as it would be represented by a line only $\frac{1}{100000}$ inch thick.

I have also marked on this diagram the approximate cost of abrasion of a gramme of material by each of the four processes, viz.:—

		£	s.	d.	
Rough grinding,	about	0	0	1	per gramme.
Fine grinding,	,,	0	0	$7\frac{1}{2}$	,,
Polishing,	,,	0	10	0	,,
Figuring,	,,	48	0	0	,,

Figuring and Testing.—By the figuring process I mean the process of correcting local errors in the surfaces, and the bringing of the surfaces to that form, whatever it may be, which will cause the rays falling on any part to be refracted in the right direction. When an objective has undergone all the processes I have described, and many more which are not so important, and with which I have not had time to deal, and when the objective is centred and placed in its cell, it is, to look at, as perfect as it will ever be, but to look through and use as an objective it may be useless. The fact is that when an objective has gone through all the processes described, and is in appearance a finished instrument, I look upon it as about one-fourth finished. Three-fourths of the work has probably to be done yet. True, sometimes this is by no means the case, and I have had instances of objectives which were perfect on the first trial; but this is, I am sorry to say, the exception and not the rule.

This part of the process naturally divides itself into two distinct heads:—

(1) The detection and localisation of faults—what may, in fact, be termed the diagnosis of the objective.

(2) The altering of the figures of the different surfaces to cure these faults. This may be called the remedial part.

It may be well here to try to convey some idea of the quantities we have to deal with, otherwise I may be misunderstood in talking of great and small errors.

I have before mentioned that it is possible to measure with the spherometer quantities not exceeding $\frac{1}{50000}$ of an inch, or with special precaution much less even than that; but useful as this instrument is for giving us information as to the general curves of the surface, it is utterly useless in the figuring process; that is, an error which would be beyond the power of the spherometer to detect, would make all the difference between a good and a bad objective.

Take actual numbers and this will be evident. Take the case of a 27-inch objective of 34 feet focus; say there is an error in centre of one surface of about 6 inches diameter, which causes the focus of that part to be $\frac{1}{10}$ of an inch shorter than the rest.

For simplicity's sake, say that its surface is generally flat; the centre 6 inches of the surface therefore, instead of being flat, must be convex and of over 1,000,000 inches radius. The versed sine of this curve, as measured by spherometer, would be only about $\frac{1}{250000}$, 4 millionths of an inch, a quantity mechanically unmeasurable, in my opinion.

If that error was spread over 3 inches only instead of 6 inches, the versed sine would only be about $\frac{1}{1000000}$. Probably the effect on the image of this 3-inch portion of $\frac{1}{10}$ inch shorter focus would not be appreciable on account of the slight vergency of the rays, but a similar error near edge of objective certainly would be appreciable. Until, therefore, some means be devised of measuring with certainty quantities of 1 millionth of an inch and less, it is useless to hope for any help from mechanical measurement in this part of the process.

If, then, no known mechanical arrangement be delicate enough to measure these quantities, how, it may be asked, are these errors detected?

The answer to this is, that certain optical arrangements enable us to carry our investigations far beyond the limits of mechanical accuracy. Trials of the objective or mirror as a telescope are really the crucial test, but there are various devices by which defects are detected and localised.

The best object to employ is generally a star of the third or fourth magnitude, when such is available, but as it frequently occurs that no such object is visible, recourse is had to artificial objects. The minute image of the sun reflected from little polished balls of speculum metal, or even a thermometer bulb is a very good object; polished balls of black glass are also used with good effect; but as the sun also is of somewhat fickle disposition in this country, we have frequently to have recourse to artificial light. Small electric lamps, such as this, with their light condensed and thrown on a polished ball are very useful. In fact, I am never without one of them in working order.

For the detection and localisation of errors it is very useful to be provided with sets of diaphragms which leave exposed various zones of the surface, the foci of which can then be separately measured, but a really experienced eye does not need them.

For concave surfaces, Foucault's test is useful. I shall not trespass on your time to explain this in detail, as it is described very fully in many works, in none better than in Dr. Draper's account of the working of his own reflecting telescope. This diagram will give an idea of the principle of the system, which is really the same as what I have described as useful for detecting want of homogeneity in the substance of the glass.

This system is extremely useful for concave spherical surfaces, but is not available for convex surfaces, and only partially available for concave parabolic surfaces.

The really crucial test is, as I said before, the performance of

the objective when used as a telescope; and the appearance of the image not only at the focus, but on each side of it, conveys to the practised eye all the information required for the detection of the errors.

If an objective have but one single fault, its detection is easy; but it generally happens that there are many faults superposed, so to speak. There may be faults of achromatism, and faults of figure in one or all the surfaces; faults of adjustment, and perhaps want of symmetry from some strain or flexure; and the skill of the artist is often severely taxed to distinguish one fault from the rest and localise it properly, particularly if, as is generally the case, there be also disturbances in the atmosphere itself, which mask the faults in the objective, and permit of their detection only by long and weary watching for favourable moments of observation.

It would be impossible in one or a dozen of such lectures as this to enumerate all the various devices that are practised for the localisation of errors, but a few may be mentioned, some of which have never before been made public.

For detection of faults of symmetry, it is usual to revolve one lens on another and watch the image. In this way it can generally be ascertained whether it is in the flint or crown lens.

With some kinds of glass the curves necessary for satisfying the conditions of achromatism and spherical aberration are such that the crown becomes an equi-convex and the flint a nearly plano-concave of same radius on inside curve as either side of the crown. This form is a most convenient one for the localisation of surface errors in this manner.

The lenses are first placed in juxtaposition and tested. Certain faults of figure are detected. Now calling the surfaces A B C D in the order in which the rays pass through them, place them again together with Canada balsam or castor-oil between the surfaces B and C, forming what is called a cemented objective. If the fault be in either A or D surface, no improvement is seen; if in B or C, the fault will be much reduced or modified. Now reverse the crown lens, cementing surfaces A and C together. If same fault still shows, it must be in either B or D. If it does not show, it will be in either A or C. From these two experiments the fault can be localised.

It often happens that a slight error is suspected, but its amount is so slight that it appears problematical whether an alteration would really improve matters or not. Or the observer may not be able to make up his mind as to the exact position of the zone he suspects to be too high or too low, and he fears to go to work and perhaps do harm to an objective on which he has spent months of labour, and which is almost perfect. In many such cases I have wished for some means by which I could temporarily alter the surface and see it so altered before actually proceeding to abrade and perhaps spoil it.

During my trials with the great objective of Vienna, I thought of a very simple expedient, which effects this without any chance at all of injuring the surface. If I suspect a certain zone of an objective is too low, and that the surface might be improved by lowering the rest of it, I simply pass my hand, which is always warmer than the glass, some six or eight times round that particular zone. The effect of this in raising the surface is immediately apparent, and is generally too much at first, but the observer at the eye end can then quietly watch the image as the effect goes off, and very often most useful information is thus obtained. The reverse operation, that of lowering any required part of the surface, is equally simple. I take a bottle of sulphuric ether and a camel's-hair brush, and pass the brush two or three times round the part to be lowered, blowing on it slightly at the same time; the effect is immediately perceived, and can always be overdone if required.

So far then for the diagnosis. Now for the remedy. When the fault has been localised, the lens is again put upon the machine and the polisher applied as before, the stroke of the machine and the size of the pitch patches being so arranged as to produce, or tend to produce, a slightly greater action on those parts that have been found to be too high (as before described while treating of the polishing processes).

The regulation of the stroke, excentricity, speed, and general action of the machine, as well as the size and proportion of the pitch squares, and the duration of the period during which the action is to be continued, are all matters the correct determination of which depends upon the skill and experience of the operator, and concerning which it would be impossible to formulate any very definite rules. All thanks are due to the late Lord Rosse and Mr. Lassell, and also to Dr. de la Rue, for having published all particulars of the process which they found capable of communication; but it is a notable fact that, as far as it is possible to ascertain, every one who has succeeded in this line has done so, not by following written or communicated instructions, but by striking out a new line for himself; and I think I am correct in saying that there is hardly to be found any case of a person attaining notable success in the art of figuring optical surfaces by rigidly following directions or instructions given or bequeathed by others.

There is one process of figuring which is said to be used with success among Continental workers. I refer to the method called the process of local touch. In this process those parts, and those parts only, which are found to be high, are acted upon by a small polisher.

This action is of course much more severe; and if only it were possible to know exactly what was required, it ought to be much quicker; but I have found it a very dangerous process. I have sometimes succeeded in removing a large lump or ring in this way (by large I mean 3 or 4 millionths of an inch), but I have also and much oftener succeeded in spoiling a surface by its use. I look upon the method of local touch as useful in removing gross quantities, but for the final perfecting of the surface I would not think of employing it.

In small-sized objectives the remedial process is the most troublesome, but in large-sized objectives the diagnosis becomes much the more difficult, partly on account of the rare occurrence of a sufficiently steady atmosphere. In working at the Vienna objective it often happened when the figure was nearly perfect that it was dangerous to carry on the polishing process for more than ten minutes between each trial, and we had then sometimes a week to wait before the atmosphere was steady enough to allow of an observation sufficiently critical to determine whether that ten minutes' working had done harm or good. It must not be supposed either that the process is one in which improvement follows improvement step by step till all is finished. On the contrary, sometimes everything goes well for two or three weeks, and then from some unknown cause, a hard patch of pitch perhaps or sudden change of temperature, everything goes wrong. At each step, instead of improvement there is disimprovement, and in a few days the work of weeks or months perhaps is all undone. Truly any one who attempts to figure an objective requires to have the gift of patience highly developed.

In view of the extraordinary difficulty in the diagnostic part of the process with large objectives, it is my intention to make provision which I hope may reduce the trouble in the working of the new 28-inch objective for the Royal Observatory, Greenwich.

Two of the greatest difficulties we have to contend with are: (1) the want of homogeneity in the atmosphere, through which we have to look in trials of the objective, due to varying hygrometric and thermometric states of various portions; and (2) sudden changes of temperature in the polishing-room. The polisher must always be made of a hardness corresponding to the existing temperature. It takes about a day to form a polisher of large size, and if before the next day the temperature changes 10° or 15°, as it often does, that polisher is useless, and a new one has to be made, and perhaps before it is completed another change of temperature occurs. To grapple with these two difficulties I propose to have the polishing-chamber under ground, and, leading from it, a long tunnel formed of highly glazed sewer-pipes about 350 feet long, at the end of which is placed an artificial star illuminated by electric light; on the other side of the polishing-chamber is a shorter tunnel, forming the tube of the telescope, terminating in a small chamber for eye-pieces and observer. About half-way in the long tunnel there will be a branch pipe connected to the air-shaft of the fan, which is used regularly for blowing the blacksmith's fire, and through this, when desired, a current of air can be sent to "wash it out" and mix up all currents of varying temperature and density. It may be found necessary even to keep this going during observations.

By this arrangement I hope to be able to have trials whenever required, instead of having to wait hours and days for a favourable moment.

Figuring of Plane Mirrors.—There is a general idea that the working of a plane mirror or one of very long radius is a more difficult operation than those of more ordinary radii. This is not exactly the case. There is no greater difficulty in figuring a low curve than a deep one, but the difficulty in the case of absolutely plane mirrors consists simply in the fact that in their figuring there

is one additional condition to be fulfilled, viz. that the general radius of curvature must be made accurate within very narrow limits. In figuring a plane mirror to use, for instance, in front of even a small objective, say 4-inch aperture, an error in radius which would cause a difference of focus of $\frac{1}{100}$ of an inch would seriously injure the performance. This would be about equivalent to saying that the radius of curvature of the mirror was about 8 miles, the versed sine of which, with the 6-inch spherometer, would be about $\frac{1}{50000}$ of an inch. Now what I mean to convey is this: that it would be just as difficult to figure a convex or concave lens of moderate curvature as a flat lens of the same size if it were necessary to keep the radius accurate to that same limit, *i.e.* one-tenth of a division of this spherometer.

Lick Observatory.—For the final testing of large objectives or mirrors, it is necessary to have them properly mounted, and in such a manner that they can be directed conveniently on any celestial object, and kept so directed by clockwork, to enable the observer to devote his whole attention to the testing. I had not intended touching at all on the subject of the mounting of telescopes, but I have been asked to call your attention to this model of a proposed observatory for Mount Hamilton, California, as it embraces some novel features, but I shall do so in only a very few words.

Most here are probably aware that a monster observatory is in course of erection in California, a large sum of money having been left for the purpose by a Mr. Lick. The observatory is already partly complete, and contains some excellent instruments of moderate size, the work already done with which warrants us to hope that the great 36-inch refractive about to be erected will be placed under more favourable conditions for work than any other large telescope in the world.

The 36-inch objective is at present in process of construction by the Messrs. Clark of America, but the mounting has not yet been contracted for.

Some years since, in a paper published in the *Transactions* of the Royal Dublin Society, I shadowed forth a principle which I considered should be adopted in great telescopes of the future. The trustees of the Lick Observatory having invited me to design an instrument for the 36-inch objective, I have put into practical form what I had before given but general principles of, and the design which this model illustrates is the result.

Whether this design will ever be carried out or not I cannot tell, but even as a proposal I trust it may be interesting enough to excuse my introducing it (somewhat irrelevantly perhaps) to your notice to-night.

The design includes the equatorial itself, with its observatory, dome, and provision for enabling the observer to reach the eye end conveniently.

The conditions I laid down for myself in designing this observatory were that it would be possible for the observer single-handed to enter the equatorial room at any time, and that, without using more physical exertion than is necessary for working the smallest-sized telescope, or even a table-microscope, he should be able to open the 70-foot dome, turn it round backwards and forwards, point the equatorial to any part of the heavens, revolving it in right ascension and declination to any extent, and finally (the most difficult of all) to bring his own person into a convenient position for observing. I say this last is the most difficult of all, for I think any who have worked with larger instruments will allow that there is generally far more trouble in moving the observatory chair (so called) and placing it in proper position than in pointing the instrument itself. In this instrument the "chair" would require to be 25 feet high, and with its movable platform, ladder, balance-weight, &c., would weigh probably some tons. Even if very perfect arrangements were made for the working of this chair, the mere fact that the observer, while attempting to make the most delicate observations, is perched upon a small and very unprotected platform 25 feet above the floor, and in perfect darkness, tends to reduce his value as an observer to an extent only to be appreciated by those who have tried it.

No matter how enthusiastic a man may be at his work, I would not put a high value on his determinations if made while in a position which calls for constant anxiety for his own personal safety. I would go even further still, and say that even personal comforts or discomforts have much to do with the value of observations.

I propose, therefore, that all the various motions should be effected by water-power. There are water engines of various forms now made, some of which have no dead point, and having little *vis inertia*, are easily stopped and started, and are consequently well adapted for this work.

I propose to use four of them: one for the right ascension motion of the instrument, and one for the declination; one for revolving the dome, and one for raising and lowering the observer himself; but instead of having anything of the nature of a 25-foot chair or scaffold, I propose to make the 70-foot floor of the observatory movable. It is balanced by counterpoise weights, and raised and lowered at will by the observer. Then the observer can without any effort raise and lower the whole floor, carrying himself and twenty people if desired, to whatever height is most convenient for observation; and wherever he is observing, he is conscious that he has a 70-foot floor to walk about on, which even in perfect darkness he can do in safety.

The valves and reversing gear of the water engines are actuated by a piece of mechanism, the motive power of which may be a heavy weight raised into position some time during the previous day by man- or water-power. By means of a simple electrical contrivance, this piece of machinery itself is under the complete control of the observer, in whatever part of the room he may be, and he carries with him a commutator of a compact and convenient form, with eight keys in four pairs, each pair giving forward and backward movements respectively to (A) telescope movement in right ascension; (B) telescope movement in declination; (C) revolution of dome; (D) raising of floor.

The remaining operation—opening of shutter—is easily effected without any additional complication.

It is only necessary to anchor the shutter (which moves back horizontally) to a hook in the wall and move the dome in the opposite direction by motion C; the shutter must, of course, be opened by this motion. . . .

It is very possible that there may be some here who have found what I have had to say on the subject of the figuring of objectives very unsatisfactory. They may have expected, naturally enough, that, instead of treating of generalities to such a large extent as I have done, I should have given precise directions, by the following of which rigidly any person could make a telescopic objective.

To those, however, who have followed me in my remarks, the answer to this will probably have already suggested itself. It is the same answer which I give to those who visit my works and ask what the secrets of the process are, or if I am not afraid that visitors will pick up my secrets. All the various processes which I have described up to that of the figuring are, I consider, purely mechanical processes, the various details of which can be communicated or described as any mechanical process can be; but in the last final and most important process of all there is something more than this. A person might spend a year or two in optical works where large objectives are made, and might watch narrowly every action that was taken, see every part of the process, take notes, and so forth, and yet he could no more expect to figure an objective himself than a person could expect to be able to paint a picture because he had been sitting in an artist's studio for the same time watching him at his work. Experience, and experience only, can teach any one the art, and even then it is only some persons who seem to possess the power of acquiring it.

A well-known and experienced amateur in this work declared his conviction that no one could learn the process under nine years' hard work, and I am inclined to think his estimate was not an exaggerated one.

True, it may be said that large objectives can be and are generally turned out by machinery, but what kind of an objective would any machine turn out if left to guide itself, or left to inexperienced hands?

At the risk of being accused of working by what is generally called the rule of thumb, I confess that conditions often arise, to meet which I seem to know intuitively what ought to be done, what crank to lengthen, what tempering is required of the pitch square; and yet if I were asked I should find it very hard to give a reason for my so doing which would even satisfy myself.

I may safely say that I have never finished any objective over 10 inches diameter, in the working of which I did not meet with some new experience, some new set of conditions which I had not met with before, and which had then to be met by special and newly-devised arrangements.

A well-known English astronomer once told me that he considered a large objective, when finished, as much a work of art as a fine painting.

I have myself always looked upon it less as a mechanical

operation than a work of art. It is, moreover, an art most difficult to communicate. It is only to be acquired by some persons, and that after years of toilsome effort, and even the most experienced find it impossible to reduce their method to any fixed rules or formulæ.

INDIAN CASTINGS AT THE INDIAN AND COLONIAL EXHIBITION

AT the last meeting of the Iron and Steel Institute Mr. C. Purdon Clarke, C.I.E., Keeper of the Indian Section, South Kensington Museum, read a paper "On Certain Descriptions of Indian Castings" as follows:—

The importation of partly manufactured material is at present exercising considerable influence over many of the native arts of Oriental countries and India. The supply of machine-made thread has doubled the village hand-looms in some districts of Madras, and gold thread from Germany has enabled the brocade weavers to compete with the imitation brocades sent in from Europe.

In some handicrafts, however, the supply of European material has produced a contrary effect. Iron and steel, bar and rod, have displaced an ancient industry, and sheet copper and brass have robbed the founder of half his work. Formerly the only means of producing sheet-metal was by hammering cast plates, an expensive method, only resorted to when thin flat coverings were required for wooden or other objects. For very large vessels, where weight was required to be kept down and strength maintained, hammered sheet was used; but generally the founder was employed, to save as much as possible the labour of forming the furnished castings which required but little beating out, trimming, and brazing.

In the case of a bowl, or flat jar with a narrow mouth, the founder would prepare a cast not unlike in shape and thickness that of an ordinary flower-pot saucer, from which, by constant hammering, the bulbous sides would be formed, projecting beyond the rim, which would remain of its first diameter and thickness. When finished, such a vessel would be nearly double the size of the first cast, and a remarkable example of the native knowledge of the composition of bronzes and annealing processes.

It is worthy of noting that the chief means of detecting modern from old Persian and Saracenic metal vessels is by examining the brazen joints, which in ancient vessels are rare. When not found, a close examination will show the vessel to be a thin casting, the ornamentation being by inlay, or chasing and hammering, which, being done after the cast is made, gives the reverse side the appearance of chased sheet metal.

So far as he could ascertain, there were three methods of casting practised in India. The first, by moulds in sand; the second, moulds in clay not unlike plasterers' piece-moulds; the third, clay moulds formed on a wax model, the *cire perdu* of Europe.

The first of these was well known in Europe, but the second was, he believed, now described for the first time. In preparing the mould, impressions of the various parts of the pattern are taken in clay, and these pieces when nearly dry are, after trimming, stuck neatly together, and kept in place by several layers of mud, in which some fibre is mixed. The mould when ready has but one vent, which, placed on the most convenient side, is carried up into a sort of bottle-neck. If the object is small, several moulds are attached together, and the vents united by a single short neck of clay, to which a crucible, inclosed in an egg-shaped ball of clay, is attached. The size of this crucible depends upon the exact amount of metal required to fill the mould or moulds; and this quantity being known by experience, the founder places it inside before closing up. No provision is made for the escape of air from the mould when the metal is poured in. The mould and crucible (now in one piece) is allowed to dry; and after several coats of clay, tempered with fibre, have also been well baked on by the sun, the furnace is prepared. This is simply a circular chamber about 2 feet 6 inches in diameter, 2 feet in height, with a perforated hearth and no chimney. Half filled with charcoal, a good heat is obtained by the use of several sheepskin bellows from beneath. When ready, as many moulds as the furnace will hold are placed in it, the crucible end of each being embedded in the fire. A cover is placed over, and the fire kept up until, upon examination, the moulds are found to be red hot. They are then taken, one at a time, and replaced in a reverse position, the crucibles being now above. The metal flows down into a red-hot mould and penetrates the finest portions of the surface without suffering from air or chilling. The fire is allowed to gradually cool, and when the objects are broken out of their clay covering, the metal is soft and malleable.

The third manner of casting (that by the use of a wax pattern which is destroyed in the moulding) was well known, but in one particular case the process had been carried further than would be at first believed, and of this he would now attempt a description.

The object produced is an anklet, a flexible ring about 4 inches in diameter, made from an endless curb chain. Such curb chain trinkets are common in India, and are generally made from thick silver wire rings interlinked and soldered one by one. In this example the anklet is of bronze, and consists of a complicated chain of forty-three detailed links, the whole being cast by a single operation. The first part of the process is the preparation of a pattern in wax, a delicate work, each link having to pass through four others, and to bear three small knobs or rosettes. These are in two instances but ornaments; the third, however, serves as a channel for the metal to enter each ring.

Then commences the most difficult part of the work, each ring having to be slightly separated, and this is effected by painting in a thin coat of fine clay until there is sufficient to form a partition. Other coats of clay are added until a thickness of about half an inch is attained, when a groove is cut round the upper side of the ring, and deepened until the row of knobs is bared. The wax is then melted out, and the mould attached to a crucible as before described. When cast, and the mould broken away, the chain comes out inflexible, being attached to a rod which runs round where the groove was cut. This is broken off, and the chain is complete.

Having been consulted respecting the trades to be represented in the Indian Courts of the Colonial and Indian Exhibition, he recommended amongst others a good brassfounder to be sent. Dr. Tyler, who was charged with the collection of these artisans, engaged one of the best he could find, but up to the present the foundry is not in working order.

One of these combined crucible moulds was submitted for inspection, with fragments of another, also a cast curb chain anklet; the author concluding by thanking the members for this opportunity of publishing an interesting process.

A NEW SPECTROMETER

IN equipping the Physical Laboratory of University College, Dundee, I felt considerable difficulty in deciding on a spectrometer for accurate work; it was easy to get a simple instrument for qualitative experiments and rough quantitative work, but it was only after consulting several friends and communicating with two or three firms that about two years ago I wrote to Mr. Hilger, in the hope that from him we might obtain an instrument capable of working to as high a degree of accuracy as would enable our best students in the laboratory to do advanced work. Considering that a second of arc is by no means an unusual limit of error in angular measurement, and that it is of the order 1 : 1,000,000, the whole circle being unit, we thought that while further capability in reading power would be more than counterbalanced by various indeterminate errors, yet it should be possible to obtain this accuracy with a suitable instrument.

Prof. Liveing was kind enough to give us valuable information about one of his own instruments, of which the plans were sent to us by Mr. Hilger for inspection; and Mr. Capstick and I finally decided to ask Mr. Hilger whether he could not arrange two microscopes on the instrument in place of the one which Prof. Liveing's has.

As a consequence, Mr. Hilger presented suggestions for a spectrometer which is now in this college, and is capable of reading directly to one second of arc and yielding reliable results. Its construction is very simple. The collimator stands on a heavy pillar by itself; and the circle, divided to five minutes of arc on a ring 15 inches in diameter, with six radial spokes, is carried on another pillar. The telescope, counterpoised, turns on the same axis, but does not touch the circle at any point; and the reading is managed as follows: from the telescope-bearing a double girder with a semicircular plan tied across its diameter by tubes of brass stretches horizontally above the semi-circumference of the divided circle; to this girder are fixed, at its ends,

two long focus microscopes, whose axes produced intersect the divided circle at the extremities of a diameter. They are read by means of a pointer and spider-line micrometer, whose head is divided into 300 parts, each of which represents one second of arc. The microscopes are carried at such a height that they easily pass the collimator, and they can be read in any position, and the light from the collimator passes clear under the girder.

J. E. A. STEGGALL

THE ABACUS IN EUROPE AND THE EAST

AT a late meeting of the Asiatic Society of Japan (reported in the *Japan Mail*), Dr. Knott read a paper on "The Abacus, and its Scientific and Historic Import." A portion of the paper described the various arithmetical processes connected with the *soroban*, the form of the abacus employed in Japan. The writer pointed out that in all arithmetical operations up to the extraction of the cube root, the *soroban* really possessed distinct advantages over ordinary ciphering. This in itself explained why the instrument, which in Europe is suggestive of an infant school, has in the East survived till the present day. The rest of the paper was a discussion of the peculiar position which the abacus, used in its widest signification, holds in the history of the progress of arithmetic and mathematics, and of science and civilisation generally. The following is an abstract of the argument, the ultimate object of which was to explain why the abacus had died in Europe but lived in China, and why the cipher system of numerals had grown up in India but not in China.

The abacus, as used in China and Japan, bears, on the surface of it, evidence of a foreign origin. The numbers are set down on it with the larger denomination to the left—a method which could hardly be believed to have been invented by the Chinese, who tend to work from right to left, and who have always named their compound numbers beginning with the higher denominations. The Chinaman says "one hundred forty-five," as the Englishman does; but the Englishman once said "one hundred five-and-forty," as the German still does; while in some of the Aryan languages of India, and in the Arabic of to-day, the number is named "five-and forty and one hundred." The Arab writes from right to left, so that, had the abacus been invented by such a people who, so to speak, both wrote and spoke inversely, it would have indicated the number as it does. In fact, the abacus could only have arisen in its present form amongst a people who either wrote and spoke directly, or wrote and spoke inversely. As a matter of history, the geographical home of the abacus is India, but, unless there is conclusive evidence to the contrary, we cannot regard it as an invention of Aryan Indians, who, although they wrote directly, spoke inversely. They probably borrowed it from the Semitic merchants, and these, with their inverse speaking and inverse writing, may have invented it, or perhaps received it from a direct-speaking, direct-writing people, such as the highly-cultured Accadians seem to have been. The abacus was evolved, no doubt, from the human hand, which, with its ten fingers, was the only counting-board used by primitive man. Its course of development is quite distinct from that of the symbolic representation of numbers. These latter we can trace through four stages, which may be called the pictorial, the symbolic, the decimal, and the cipher. The pictorial we find in the Egyptian hieroglyphic and the Accadian cuneiform; the symbolic in the hieratic, Phœnician, Hebrew, Greek, Roman, and the host of systems which grew up with the development and spread of alphabets and syllabaries, and the decimal in the simplification of these which live to-day in the Chinese and Tamilic systems. Once the decimal stage was reached, its general similarity to the abacus indications suggested bringing them into still closer correspondence. This took place amongst the Aryan Indians, who, along with their brethren of the West, very soon discarded the abacus for the, to them, more convenient cipher notation. With the Chinese and Tamils, however, no advance was made in this direction, a fact especially surprising in the case of the latter, who have lived in close contact with peoples that have long used the cipher system of numerals. One reason for the Chinese conservatism in so adhering to an unwieldy notation might be their vertical mode of writing, with which no very striking similarity between their symbolising of numbers and the abacus columns would appear. But this does not explain the conservatism of the Tamils, who write from left to right, nor yet the persistence of the abacus for centuries face to face with the Indian cipher system. The explanation is rather to be found in the system of nomenclature, which, being direct both among the Chinese and the Tamils, fitted perfectly with the abacus indications. For this reason the manipulation of the abacus in China and Japan is more rapid and certain than ciphering, and hence, there being no advantage for simple arithmetical operations in the latter, the cipher system did not develop in these countries, and even when introduced from the West in all its vigour could not displace "the rod and the beads." An Aryan Indian, with his inverse-speaking, could never work the abacus with the same facility as the Japanese unless he worked from right to left, a mode of procedure quite foreign to his nature. It is not so foreign to the Chinese and Japanese, however, to work from left to right, as shown in the formation of each individual ideograph employed in writing. Hence the abacus suited the Chinese language better than it did any of the Aryan languages in their original mode of number-naming. The influence of the notation which was developed from Semitic sources under the influence of the abacus, has in later times compelled many of the Aryan languages to assimilate as far as possible to the direct mode of numeration; but in the English *fifteen*, the German *fünfzehn*, and the French *quinze*, we still have the relics of the original inverse mode of naming, alike peculiar to Aryan and Semitic peoples.

In the course of the discussion which followed, it was mentioned that Chinese mathematics were first studied in Japan about 900 A.D., and that the Japanese ascend by powers of 10,000 in their treatment of larger numbers.

THE GAZETTEER OF RUSSIA[1]

WE have received the concluding fascicule of the "Geographical and Statistical Dictionary of the Russian Empire," published by the Russian Geographical Society, and edited by M. P. Semenoff. This monumental work, which was begun more than twenty years ago, has been now concluded in five large octavo volumes, and will remain for many years the most trustworthy and complete source of information for the geography of the empire, exclusive of Poland, but inclusive of the former Russian dominions in America. It may be regretted that the editor of the "Dictionary" has been diverted by so great a variety of geographical, statistical, and administrative work from this undertaking, and that therefore the last fascicule appearing twenty-three years after the first, the statistical information contained in the first fascicules and volumes has become out of date. But notwithstanding that, the "Dictionary" has not become old. Its value is not in the statistical data it contains; it is much more in the excellent geographical descriptions of the localities treated—that is, of each separate government of Russia, Siberia, Turkestan, and Caucasus—of the seas that border Russia, and their islands. Several articles are excellent and most complete monographs, and we need only mention those on the Amur, Caucasus, Sakhalin, the Northern Ocean, or Turkestan to remind geographers of these excellent descriptions of whole regions. The geology, the flora and fauna of each region have received much attention. These descriptions will not soon be old—they can be only completed.

At the end of each article there is, moreover, a most complete bibliography of the larger geographical works in which the place described in the article has been mentioned, as also of monographs dealing with it, and of newspaper articles. This bibliography is invaluable for the geographer. On the whole, the equally high standard of all geographical descriptions and the unity of conception in all of them—the whole being the work of the editor himself, assisted only by M. Zverinsky and very few occasional contributors—make this "Dictionary" occupy one of the first ranks among like publications. An appendix is promised, which will contain descriptions of such regions as the Thian-Shan, Ferganah, and Transbaikalia, which were much explored during the publication of the "Dictionary." They will embody all recent information.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CONVOCATION of the University of London met on Tuesday evening to consider the report of a Special Committee which proposed several important changes in the constitution of the

[1] "Geographitchesko-Statistitcheskiy Slovar Rossiyskoy Imperii,' P. P. Semenova.

University. After considerable discussion, resolutions were passed approving of the admission of certain educational institutions having one, or more than one, faculty of University rank as constituent Colleges of the University, of the establishment of a Council of Education, and of certain changes in the constitution of the Senate.

SCIENTIFIC SERIALS

THE most important paper in the *Journal of Botany* for April is the commencement of a Synopsis of the Rhizocarpeæ, by Mr. J. G. Baker, another of the series of this writer's exhaustive monographs of the families of Vascular Cryptogams outside the Ferns. The present instalment includes the genus Salvinia, in which three new species are described, and a portion of Azolla. In the May number we find a continuation of Mr. W. B. Grove's paper on new and noteworthy fungi, in which several new species are described, and one new genus of Sphæroideæ, Collonema. Mr. W. H. Beeby gives further particulars respecting the distribution of his newly discovered *Sparganium neglectum*, and Mr. Arthur Bennett an account of the distribution in Britain of the various species of Potamogeton, in addition to those contained in the second edition of "Topographical Botany."

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 20.—"Relation of 'Transfer-Resistance' to the Molecular Weight and Chemical Composition of Electrolytes." By G. Gore, LL.D., F.R.S.

In the full paper the author first describes the method he employed for measuring the "resistance," and then gives the numerical results of the measurements in the form of a series of tables.

He took a number of groups of chemically related acids and salts of considerable degrees of purity, all of them in the proportions of their chemical equivalent weights, and dissolved in equal and sufficient quantities of distilled water to form quite dilute solutions. The number of solutions was about seventy, and included those of hydriodic, hydrobromic, hydrochloric, hydrofluoric, nitric, and sulphuric acids; the iodides, bromides, chlorides, fluorides, hydrates, carbonates, nitrates, and sulphates, of ammonium, cæsium, rubidium, potassium, sodium, and lithium; the chlorides, hydrates, and nitrates, of barium, strontium, and calcium; and a series of stronger solutions, of equivalent strength to each other, of the chlorides of hydrogen, ammonium, rubidium, potassium, sodium, lithium, barium, strontium, and calcium. A series of similar liquids to those of one of the groups of acids, of equal (not of equivalent) strength to each other, was also included.

As electrodes, he employed pairs of plates of zinc, cadmium, lead, tin, iron, nickel, copper, silver, gold, palladium, and platinum; and separate ones formed of small bars of iridium.

He took each group of solutions, and measured in each liquid separately, at atmospheric temperature, the "total resistance" at the two electrodes, and the separate "resistances" at the anode and cathode respectively with each other, and thus obtained about seventy different tables, each containing about thirty-six measurements, including the amounts of "total," "anode," and "cathode" resistance of each metal, and the "averages" of these for all the metals.

By comparing the numbers thus obtained, and by general logical analysis of the whole of the results, he has arrived at various conclusions, of which the following are the most important:—The phenomenon of "transfer-resistance" appears to be *a new physical relation of the atomic weights*, attended by inseparable electrolytic and other concomitants (one of which is liberation of heat, *Phil. Mag.*, 1886, vol. xxi. p. 130). In the chemical groups of substances examined *it varied inversely as the atomic weights of the constituents, both electro-positive and electro-negative, of the electrolyte, independently of all other circumstances*; and in consequence of being largely diminished by corrosion of the electrodes, it appeared to be intimately related to "surface-tension." He suggests that corrosion may be a consequence, and not the cause of small "transfer-resistance." The strongest evidence of the existence of the above general law was obtained with liquids and electrodes with which there was the least corrosion and the least formation of films; those liquids were dilute alkali-chlorides, with electrodes of platinum.

This research is an extension of a former one on "Transfer-Resistance in Electrolytic and Voltaic Cells," communicated to the Royal Society, March 2, 1885. Further evidence on the same subject has been published by the author in the *Philosophical Magazine*, 1886, vol. xxi. pp. 130, 145, 249.

"A Study of the Thermal Properties of Ethyl Oxide." By William Ramsay, Ph.D., and Sydney Young, D.Sc.

A year ago a paper was communicated to the Society on the behaviour of ethyl alcohol when heated. A similar study of the properties of ether has been made, in which numerical values have been obtained exhibiting the expansion of the liquid, the pressure of the vapour, and the compressibility of the substance in the gaseous and liquid conditions; and from these results, the densities of the saturated vapour and the heats of vaporisation have been deduced. The temperature range of these observations is from $-18°$ to $223°$ C.

It is the authors' intention to consider in full the relations of the properties of alcohol and ether; in the meantime it may be stated that the saturated vapour of ether, like that of alcohol, possesses an abnormal density, increasing with rise of temperature and corresponding rise of pressure; that at 0° the vapour-density is still abnormal, but appears to be approaching a normal state; and that the apparent critical temperature of ether is 194° C.; the critical pressure very nearly 27,060 mm. = 35·61 atmospheres; and the volume of 1 gramme of the substance at 184 between 3·60 and 4 c.c.

Mathematical Society, May 13.—J. W. L. Glaisher, F.R.S., President, in the chair.—Mr. F. W. Watkin was admitted into the Society.—The following communications were made:—On Cremonian congruences contained in linear complexes, by Dr. Hirst, F.R.S.—Solution of the cubic and biquadratic equation by means of Weierstrass's elliptic functions, by Prof. Greenhill.—On the complex of lines which meet a unicursal quartic curve, by Prof. Cayley, F.R.S.—On Airy's solution of the equations of equilibrium of an isotropic elastic solid under conservative forces, by W. J. Ibbetson.—Conic note, by H. M. Taylor.—On the converse of stereographic projection and on contangential and coaxal spherical circles, by H. M. Jeffery, F.R.S.

Zoological Society, May 18.—Prof. W. H. Flower, F.R.S., President, in the chair.—Mr. C. W. Rosset exhibited a series of photographs taken during his recent visit to the Maldive Islands, and made some remarks on the zoological collections obtained during his expedition.—Mr. Philip Crowley, F.Z.S., exhibited some pupæ of nocturnal Lepidoptera which had been sent to him from Natal; and read some notes from his correspondent, which proved that they were subterranean.—Mr. Joseph Whitaker, F.Z.S., exhibited a specimen of Wilson's Phalarope, said to have been obtained at Sutton Ambian, near Market Bosworth, in Leicestershire.—A communication was read from Dr. A. B. Meyer, C.M.Z.S., containing an account of the known specimens of King William the Third's Bird of Paradise (*Rhipidornis gulielmi-tertii*), and remarking on a fourth specimen which had been recently obtained by the Dresden Museum.—Mr. Frank E. Beddard read a paper on some new or little-known Earthworms, together with an account of the variations in structure exhibited by *Perionyx excavatus*.—Mr. Sclater read a paper on the species of Wild Goats and their distribution. Mr. Sclater recognised ten species of the genus Capra, distributed over an area extending from Spain to Southern India, and from Central Siberia to Abyssinia.

Royal Meteorological Society, May 19.—Mr. W. Ellis, F.R.A.S., President, in the chair.—Mr. L. T. Cave and Rev. C. Malden, M.A., were elected Fellows of the Society.—The following papers were read:—The severe weather of the past winter, 1885–86, by Mr. C. Harding, F.R.Met.Soc. The author showed that the whole winter was one of exceptional cold, not so much on account of any extremely low temperatures experienced, but more from the long period of frost and the persistency with which low temperature continued. In the South-West of England there was not a single week from the commencement of October to March 21 in which the temperature did not fall to the freezing-point. In many parts of the British Islands frost occurred in the shade on upwards of 60 nights between the beginning of January and the middle of March, and during the long frost which commenced in the middle of February and continued until March 17 the temperature fell below the freezing-point in many places on more than 30 consecutive nights. At Great Berkhamsted, in Hertfordshire, frost

occurred on the grass on 73 consecutive nights from January 5 to March 18. The winter of 1885–86 was the only one in which there was skating on the water of the London Skating Club, in Regent's Park, in each of the four months December to March, since the formation of the Club in 1830, and there are but four records of skating in March during the 56 years, and none so long as in the present year. With regard to the temperature of the water of the Thames at Deptford, it was shown that the total range from January 8 to March 20 was only 6°, whilst from March 1 to 19 the highest temperature was 36°·5, and the lowest 35°. The temperature of the soil at the depth of 1 foot was generally only about 2° in excess of the air over the whole of England, and from March 1 to 17 the earth was colder than usual by amounts varying from 6°·3 at Lowestoft to 8°·5 at Norwood. The facts brought together showed that the recent winter was one of the longest experienced for many years, and that in numerous ways it may be characterised as "most severe."—Description of an altazimuth anemometer for recording the vertical angle as well as the horizontal direction and force of the wind, by Mr. L. M. Casella. The author describes an anemometer he has made which records continuously on one sheet the pressure, direction, and inclination of the wind.—Earth temperatures, 1881–85, by Mr. W. Marriott, F.R.Met.Soc. This is a discussion of the observations of the temperature of the soil at various depths below the surface, which have been regularly made at 9 a.m. at several of the stations of the Royal Meteorological Society during the past five years. The results show that the temperature of the soil at 1 foot at nearly all the stations in the winter months is almost the same as that of the air, while in the other months of the year the temperature of the soil is higher than that of the air at all except that of the London stations.—Note on the after-glows of 1883–84, by Mr. A. W. Clayden, M.A., F.R.Met.Soc. The author suggests that the after-glows were the result of the water-vapour erupted from Krakatão, and that the dust and other ejecta played but a secondary part in the production of the phenomena.

Sydney

Linnean Society of New South Wales, March 31.—Mr. William A. Haswell, M.A., B.Sc., in the chair.—The following papers were read:—On certain Geckos in the Queensland Museum, by Charles W. de Vis, M.A. A new species of the very curious genus *Nephrurus* is described under the specific name of *lævis*, from its smooth lepidosis, as compared with the only other species, *N. asper*. A species of *Diplodactylus* (*D. venicauda*) is also described. Both lizards are from Northern Queensland.—Description of a new aphanipterous insect from New South Wales, by A. Sidney Olliff, F.E.S., Assistant Zoologist, Australian Museum. The remarkable parasite here characterised under the name *Echidnophaga ambulans* was found in large numbers on the head and breast of a porcupine anteater (*Echidna hystrix*). It differs from the *Pulex echidnæ* described by Denny from the same host in habit as well as in several important points of structure, and is, therefore, regarded as forming the type of a new genus. Unlike the majority of its allies this species does not appear to possess the power of jumping.—On a microscopic fungus parasitic on the Cucurbitaceæ, by E. Haviland, F.L.S. In this paper the author gives an account of his inquiry as to the origin of a disease which has caused much destruction to melon and pumpkin plants during the last three months, and which he has identified as the micro-fungus *Oidium monilioides*. As a preventative he suggests greater care in cultivation, and quotes various authors proving that old plants will thereby be sufficiently vigorous to resist the attacks of the fungus.—Jottings from the Biological Laboratory of Sydney University, by William A. Haswell, M.A., B.Sc., Lecturer on Zoology and Comparative Anatomy. On the myology of the flying squirrel (*Petaurista taguanoides*). In its muscular anatomy the flying phalanger nearly resembles the vulpine phalanger and the *Cuscus*, with a few special modifications, of which the chief is the presence of a peculiar "long femoro-caudal muscle."—Insects of the Fly River, New Guinea, "Coleoptera," by William Macleay, F.L.S., &c. This is the second paper communicated by Mr. Macleay on the insects collected during the recent expedition organised by the Geographical Society of Australia for the exploration of the interior of British New Guinea. The previous paper dealt with the Coleoptera up to the end of the Heteromera. The present one deals with the families *Curculionidæ*, *Brenthidæ*, *Anthribidæ*, and *Longicornia*, comprising in all 96 species, of which 31 are now described for the first time.—The Mollusca of the Pareora and Oamaru systems of New Zealand, by Capt. F. W. Hutton, Hon. Member Linnean Society, New South Wales. Capt. Hutton's paper is a contribution towards the correlation of the Tertiary rocks of Australia with those of New Zealand, and it enumerates 268 species of Mollusca from the Pareora and Oamaru systems, which are probably of Miocene and Oligocene age, of which 184 species are confined to the Pareora beds, 33 species to the Oamaru, while 51 species, of which a few are doubtful, are common to both.

Paris

Academy of Sciences, May 17.—M. Jurien de la Gravière, President, in the chair.—Presidential allocution on the occasion of the homage offered to M. Chevreul at the meeting of Monday, May 17, when that illustrious member and *doyen* of the Academy completed his hundredth year. In reply, M. Chevreul assured the audience that to be told his long career had been useful to science and his country was the greatest eulogium he had ever ambitioned.—Observations in reference to the quantitative analysis of the ammonia found in the ground: a reply to M. Schlœsing, by MM. Berthelot and André. The authors point out that the note recently published by them in the *Comptes rendus* was not intended to raise any discussion on M. Schlœsing's theories regarding the absorption of atmospheric ammonia by arable lands. Their main object was to explain a special precaution and a common source of error in the quantitative analysis of the ammonia present in the ground. Nor did they wish to deny that the ground receives in a general way a supply of ammonia from the atmosphere, although they did not consider that this fact had been fully demonstrated by M. Schlœsing's experiments.—Reply to M. Taurines's recent observations on the communication of March 23, 1885, regarding marine engines and the experiments made on board the *Primauguet*, by M. A. Ledieu. The author maintains the general correctness of his conclusions, which are unfairly stigmatised by M. Taurines as "theories conceived *a priori* and at times dangerous."—Remarks on the third volume of the Scientific Mission to Cape Horn, presented to the Academy by M. Mascart. This volume contains all the observations regarding terrestrial magnetism, and MM. Müntz and Aubin's analyses of the specimens of atmospheric air collected by Dr. Hyades. The researches on terrestrial magnetism were greatly aided by a continuous registering apparatus, which was set up by MM. Payen and Le Cannellier, and which worked satisfactorily the whole time the Mission remained in Orange Bay. Incidental reference was made to the subsequent death of M. Payen in France, and of M. Martial, commander of the Expedition, in China.—Elements of the orbit of Brooks's comet, No. 1, by M. Lebeuf. These elements, deduced from observations made at Kiel on April 30, and at Paris on May 4 and 8, are as under:—

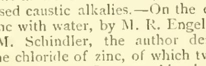
$$T = 1886 \text{ June } 7{\cdot}5158 \text{ Paris Mean Time.}$$

$$\left.\begin{aligned} \Omega &= 193^\circ\ 1'\ 29''{\cdot}5 \\ \varpi &= 33\ \ 42\ \ 7{\cdot}1 \\ i &= 87\ \ 47\ \ 34{\cdot}7 \end{aligned}\right\} \text{Mean Eq. } 1886{\cdot}0.$$

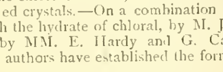
$$\log q = 9{\cdot}439104$$

—Observations of Brooks's comets made at the Observatory of Algiers with the 0·50 m. telescope, by M. Rambaud.—Measurement of the electric conductivity of the dissolved chloride of potassium, by M. E. Bouty. Between the temperatures of 0° C. and 30° C. the resistance of the solutions of the chloride of potassium is expressed with sufficient accuracy by the binomial formula $r_t = \dfrac{r_0}{1 + \alpha t}$. A table is given of the absolute values of the specific resistance r_0 and the relative values of the molecular resistance ρ_0, as well as the values of α.—On the atomic volume of oxygen, by M. E. H. Amagat. M. Wroblewski having recently announced that the atomic volume of oxygen was considerably below 16, the author points out that he had arrived at the same conclusion early in 1885. In his communication of March 2 of that year he stated that under a pressure exceeding 4000 atmospheres he had succeeded in obtaining oxygen with a density higher than 1·25 and at a temperature of 17°.—Observations on the deviation from the vertical on the south coast of France, by M. Germain. From four determinations obtained at Nice, Saint-Raphael, Toulon, and Marseilles, the author infers that on this seaboard the continent attracts the vertical, that is to say, repels the astronomic as opposed to the geodetic zenith, and that this attraction

appears to be exercised by a point situated to the north of Nice in the Alps.—On the barometric pressure of May 13, 1886, when at 4 o'clock in the morning the barometer fell to 737·37 mm., the lowest recorded in Paris since the year 1757, by M. E. Renou. This remarkable fall coincides with violent atmospheric disturbances in Madrid and other parts of Spain, in England and the United States. The stormy weather reached Italy and Germany on May 14, when the Jura and Chaux-de-Fonds were covered with snow.—Action of vanadic acid on the ammoniacal salts (continued), by M. A. Ditte. In this paper the author deals with a second group comprising the sulphate, chromate, iodate, borate, acetate, vanadate, perchlorate, carbonate, and hydrochlorate of ammonia.—On several double silicates of alumina, and of potassa or soda, by M. Alex. Gorgeu. The kaolin with which these silicates are obtained is that used at the Sevres works. This composition when dried at a temperature of 120° C. is almost exactly that of the silicate of hydrated alumina, $2SiO_2Al_2O_3,2HO$. Its action is described on the alkaline haloid salts, on the alkaline carbonates, and on the fused caustic alkalies.—On the combinations of the chloride of zinc with water, by M. R. Engel. Besides that discovered by M. Schindler, the author describes three other hydrates of the chloride of zinc, of which two may be obtained in large isolated crystals.—On a combination of phosphuretted hydrogen with the hydrate of chloral, by M. J. de Girard.—On pilocarpine, by MM. E. Hardy and G. Calmels. For this substance the authors have established the formula—



and for pilocarpidine—



—Researches on the composition of carotine, its chemical function, and its formula, by M. A. Arnaud. This is a carburet of hydrogen ($C_{26}H_{38}$) identical with the orange-red crystallised substance which the author has extracted from the leaves of various kinds of plants. This colouring-matter exists also in a great many fruits, and especially in the tomato, and may in fact be said to be universally present in the roots, leaves, and fruits of plants. It oxidises in the air even at the ordinary temperature, and especially about 70° C., and in solution this oxidation becomes extremely rapid.—Remarks on the bilobites, by M. Stan. Meunier. The author makes a fresh study of these interesting vestiges, without deciding the question whether they are mere animal footprints, as supposed by M. Nathorst, or real fossil algæ, as maintained by MM. Delgado and De Saporta.—Characteristics of the stem of Poroxylon (fossil gymnosperms of the Carboniferous epoch), by MM. C. Eg. Bertrand and B. Renault.—Account of a meteor recently observed on board the steamer *Algérie* in the Gulf of Smyrna, by M. L. Aubouy.

BERLIN

Physiological Society, April 30.—Dr. Wolffberg spoke on the Young-Helmholtz theory of the colour-sense, which he extended in the direction of assuming the existence of red-sensitive, green- and violet-sensitive ganglia in the central organ of sight-perception in the sphere of vision. These ganglia were connected with the red nerves, the green nerves, and the violet nerves, and by means of such nerves communicated with the retina. Seeing, however, that yellow, blue, and white were likewise psychically simple sensations, Dr. Wolffberg assumed specific ganglia for these as well, which, however, stood in connection with the red, green, and violet ganglia, the yellow ganglia being situated at an equal remove from the red and green, but at a further remove from the violet ganglia. Similar was his conception of the situation and connection of the blue and white ganglia. Regarding the sensation of black, he would speak in an address in the immediate future.—Dr. Uhthoff made further communications respecting the dependence of visual sharpness on the intensity of illumination. After an historical survey of the older experiments to determine the relation of visual sharpness to light intensity, he described the results of his own labours in this field. In the case of white light, he had communicated the relation on a former occasion (NATURE, vol. xxxi. p. 476). In the case of yellow light, the visual sharpness under low intensities increased just as rapidly with increasing intensity of light as in the case of white light. The curve, however, in the former case attained a greater height than it did with white, and then likewise proceeded parallel to the abscissa. With red light, on the other hand, the curve kept below the height reached with white light; it rose slower, moreover, and never became parallel. The curve of visual sharpness for green light lay still deeper than for red, and also rose persistently, though slowly. The curve for blue light lay deepest of all, and very soon became parallel to the abscissa of the light intensity. In the case of a green-blind person, the curves for white, yellow, and red were the same as in the case of the normal eye, as there was likewise a coincidence for blue. The curve for green fell almost coincident with the low curve for blue.

BOOKS AND PAMPHLETS RECEIVED

"Contra-Indications for Visiting the High Altitudes," with a Description of the Environs of Maloja, by Dr. A. T. Wise (Churchill).—"The Pictorial Arts of Japan," part ii., by Wm. Anderson (S. Low).—"Bees and Bee-keeping," part ix., by F. R. Cheshire (U. Gill).—"Fancy Pigeons," 3rd edition, part ix., by J. C. Lyell (U. Gill).—"British Cage Birds," part ix., by R. L. Wallace (U. Gill).—"Bicycles and Tricycles of the Year 1886," by H. H. Griffin (U. Gill).—"Mineralogical Magazine," March.—"Journal of Physiology," April.—"Proceedings of the Physical Society, St. Petersburg," vol. xviii. part 4.—"Bulletin de l'Académie Impériale des Sciences de St. Petersburg," vol. xxxi. No. 1.—"Chemical Atlas," part 1, by C. Peddie (Thin, Edinburgh).—"The Baths, Bathing, and Attractions of Aix-les-Bains," by Dr. W. Wakefield (S. Low).—"Bulletin of the United States Fish-Commission," vol. v., for 1885 (Washington).—"Causeries Scientifiques," by Hy. Vivarez (J. Michelet, Paris).—"Proceedings of the American Philosophical Society," April.—"American *versus* English Methods of Bridge Designing" (Japan Mail).—"Third Report on the Chemical Composition and Physical Properties of American Cereals, Wheat, Oats, Barley, and Rye," by C. Richardson (Washington).—"Memoir of Arnold Guyot, 1807 to 1884," by J. D. Dana.

BRITISH FUNGI

Hymenomycetes Britannici—British Fungi (*Hymenomycetes*). By Rev. John Stevenson, Author of "Mycologia Scotica." Vol. I. Agaricus—Bolbitius. 8vo, pp. 372, with Cuts. (Edinburgh: William Blackwood and Sons, 1886.)

A QUARTER of a century ago, the number of persons in this country who made any pretence to study the fungi might have been counted on the fingers, and almost on the fingers of one hand. At that time Berkeley's "Outlines of British Fungology" had just appeared, but with it came no visible evidence of an increased number of students. An unfortunate desire to limit the volume to a definite size and price acted injuriously upon its contents. Half the book was a mere list of names without descriptions, and in the other half the descriptions were reduced to short diagnoses, quite insufficient except for those who were somewhat expert in the study. The young student struggling to get some knowledge of these obscure plants had no alternative but to fall back on the supplementary volume of Hooker's "English Flora" for the information he needed, oftentimes with much disappointment. Hence it is not surprising that only a few had the courage to persevere in a study for which there was no adequate text-book. It was not until 1871 that Cooke's "Hand-book of British Fungi" supplied what was required, and imparted a stimulus to the pursuit of that section of British botany, which has gradually increased in force, until at the expiration of another fifteen years, the "Hand-book" is out of print, and out of date, with a greatly augmented body of students looking anxiously for a new edition, or an entirely new work.

At this crisis, and under these circumstances, the work now before us has made its appearance, opportunely, and it is to be hoped satisfactorily, to fill a vacant place. No apology is offered, and none is required, where there is no rivalry, and a manifest necessity has been created by the flux of time. If the new work fulfils all the conditions of such a "Hand-book" of mycology as the student would require, there is a good and valid case in its favour. It must be conceded that although his previous "Mycologia Scotica" was little more than a localised catalogue, there was every reason to believe that the Rev. John Stevenson would bring practical experience and literary ability to his task, and acquit himself well in the production of a more elaborate work. In the result his friends have no reason to be disappointed. He has laboured conscientiously, and although in some things we do not agree with him, has accomplished a useful task.

It is hinted in the preface, although not clearly stated, what is the character of the book, namely, that it is practically a translation of Fries's "Monographia" in so far as the British species are concerned. There is no doubt that this was the best course to adopt, because there can be no two opinions of the value of Fries's observations, and the book in which they are written is very rare, and beyond the reach of the ordinary student. Still it would have been better not to have left this point in suspense, since a long detailed description which can be attributed without reservation to Fries is of infinitely more value than the most careful compilation would be. Unfortunately, any one who opens the book to consult it for the first time will at once conclude that the descriptions are the original production of the author, whose name appears on the title-page. We do not for a moment imagine that there was any desire to appropriate wholesale and take credit for the product of another man's brains, but unfortunately that *is* done sometimes in scientific books, and an honest author should be above suspicion.

Of the type, paper, and general appearance of the work, including the woodcuts by Mr. Worthington Smith, we have nothing to say except in strong commendation. But we cannot help quoting one sentence from the preface, which at least is original—"The tendency in recent years has been to multiply species unnecessarily, and ultimately many so-called species must disappear. The pruning-knife must be unsparingly used; but this must be the work of a Congress of Cryptogamic Botanists, not of individual authors." This quotation is made without intention of dissenting from it, but as a prelude to a statement of the fact that in the present volume two sub-genera and about fifty species (good, bad, or indifferent) which have been recorded as British, some on the authority of the Rev. M. J. Berkeley, and many of them figured, are entirely excluded without comment or apology. Was this "the work of a Congress of Cryptogamic Botanists or of an individual author?"

Some writers, and compilers, of the present day exercise a questionable originality in the correction, or alteration, of the orthography of generic names which have been in use for, perhaps, half a century. No useful purpose is served, except the gratification of personal vanity, and the multiplication of synonymy. We note, on p. 304, an instance of this kind, where *Psalliota* is written *Psaliota*. Without inquiring which is most accurate, or most elegant, surely its uniform use by Fries, in the previous form, since 1821, should have been sufficient to protect it from the "pruning-knife," and given it some title to usage in perpetuity. To such manipulators of names we would commend the following sentence from De Candolle's Commentary on the Laws of Botanical Nomenclature:—"In these kinds of questions, it must be borne in mind that the fixity of names is of superior importance."

We observe also two or three instances in which the orthography of specific names has undergone a change, but as it is just possible that these may be referred to typographical errors, and not to any intentional mutilation, we will accord the author the benefit of the doubt.

Some apology is made in the preface for a departure in the present work from the ordinary method of giving first a short diagnosis of the species, and afterwards a detailed description. "I am aware," it says, "that the departure from this method will touch existing prejudice; but it seems desirable to avoid repetition, to the extent of one-third, or one-half, in the account of each species, and thereby to secure space for fuller description. Moreover the *diagnosis* is not lost. From the arrangement which is adopted in printing, the student, if he is a student at

all, can at a glance pick it out for himself." We confess that we are not conscious ourselves of any prejudice which this arrangement touches inconveniently, since the diagnoses, by themselves, can be obtained in another form.

This first volume extends to the end of the genus *Bolbitius;* a second volume is proposed to complete the work, embracing all the British Hymenomycetes. Thus far we have descriptions of 822 species, corresponding to 485 which were included in the "Hand-book of British Fungi" in 1871, and 383 in Berkeley's "Outlines" in 1860; whilst all the European species included in Fries's "Hymenomycetes" up to the same point was 1271. Hence it would appear that two-thirds of the species enumerated by Fries as European have been found in the British Isles. This may not be absolutely accurate, since there are some included in the present volume which are not to be found in Fries, but the proportion is small and will not much affect the ratio. It is an interesting fact that the number of British species has been nearly doubled in fifteen years, which at least must be taken to indicate a larger number of observers and increased activity, for which there was doubtless some good and sufficient cause. Although coloured figures of upwards of 700 out of the 822 species have been published in this country since 1881, that would scarcely have been an appreciable factor in the result.

Criticisms of particular species would prove of little interest to any but practical mycologists, and therefore we forbear. In these times, when authority is held to have such slender claims, and independence of opinion is esteemed more highly than respect for the convictions of the old masters, it is a great consolation to encounter such an earnest and faithful disciple of the good old mycologist of Upsal as we meet with in the author of the book before us. Yet, notwithstanding this good trait, he has evidently a weak place in his human nature, without the tact to conceal it, and this is to be regretted, since rancour—like young chickens—comes home to roost.

A MEDICAL INDEX-CATALOGUE

Index Catalogue of the Library of the Surgeon-General's Office, United States Army. Vol. VI. Heastie–Insfeldt. (Washington: Government Printing-Office, 1885.)

AMONGST the vast and rapidly-increasing mass of scientific literature it is a singular satisfaction to meet with a first-rate work such as this "Index Catalogue," which holds out good promise of being a clue to some parts at least of what is far too large for any single grasp. And if in any department of science it is more important than in another to trace generalisations to their foundations upon observations, and to have the facts before one, it is in medicine, which still contains so many dogmas whose foundations are not beyond attack, and so many observations in want of an adequate theory to explain them. In giving a clue to medical knowledge this "Index Catalogue" is in one respect at least, and in one very important respect, unique among its class; for under subject-headings such as, in this volume, hernia, hooping-cough, hydrophobia, hip-joint, hospitals, hygiene, insanity, &c., it gives a list not only of all the books and pamphlets in the library dealing with them, but also a list of the full titles of all the articles on them in all the periodical literature that it possesses, *Journals*, *Transactions*, *Reports*, *Reviews*, *Bulletins*, &c.; and when we reflect that the list of such periodicals taken in by the Surgeon-General's Office amounts now to at least 3005 (of which a very considerable proportion are weekly or monthly publications), such a careful classification of their separate articles would seem to be beyond all hope. However, the unexampled energy of Mr. J. S. Billings and his able assistants, which gives us every month the *Index Medicus*, has proved equal to this gigantic task, which it would have seemed to most men mere foolishness to attempt. The advantage to the student is immense; for in such periodical literature, by modern fashion, a great number of important facts in medicine lie buried, and there would hardly be a chance of finding them without some such help as is given us here. For though the literature of science is far less at present in bulk than the literature of some other subjects, most notably divinity, yet the literature of natural science, even in one of its many subdivisions, such as medicine, is paralysing in its profusion. To take as an instance the literature of a disease which, though just at present it is the fashion to talk much about it, is yet so rare that many doctors with considerable experience have never seen it, viz. hydrophobia, we find catalogued here not only 368 books dealing with it specially, but also the full titles of more than 1900 signed articles, not in the general but the medical press of the European languages, that have to do with it as well; and yet that is not a fifth part of what is catalogued under "Cholera" in Vol. III., and not a tenth of what is catalogued under "Fever" in Vol. V. The subdivision and arrangement of the masses of information so gathered together is admirable, and that, for subjects so difficult to deal with as hospitals and hygiene, which occur in this volume, is not a little to be proud of, and one that any student will appreciate. To the accuracy of every entry it would be absurd to pretend to testify on our own investigation, but frequent use of the five preceding volumes and some testing of this sixth volume leave us in little doubt that a very high standard was previously reached, and will be found to be maintained, and of course that is one of the points of cardinal importance in what is practically a dictionary of reference.

The Washington Library, or, as we should say more accurately, the "Library of the Surgeon-General's Office, United States Army," is one of the two or three largest collections of medical books in the world, and its growth has been astonishingly rapid. It was begun in 1830, and, after the first thirty years, in 1860, it contained only 350 volumes. To what size, at the end of the next thirty years, in 1890, we may see it grow we hardly venture to speculate; but in 1883 it stood at about 60,000 books and 66,000 pamphlets, and took in more than 2600 periodicals; and yet a careful critic last year estimated that for every hundred medical books that were in both the Washington Library and the British Museum there were also another hundred in each that were not in the other. If that be true, it would not astonish us to hear that for every hundred held in common there were fifty or more in the Bibliothèque Nationale at Paris, which were not to be

found in either of them. The largest medical specialist library in England, that of the Medical and Chirurgical Society, cannot claim to be more than half the size of the Washington Library, or to contain many books that are not to be found elsewhere; and it does not grow with all the rapidity of the New World.

For some time probably all seekers after the most difficult and most complete medical knowlege will have to turn to this "Index Catalogue," and will trust that Mr. Billings may be able to go on year after year putting forth his modest quarto of 1000 pages, until six or seven years may see him at the end of his great work.

A. T. MYERS

OUR BOOK SHELF

Mémoires de la Société des Sciences Physiques et Naturelles de Bordeaux. 3e série, tome i. (Paris: Gauthier-Villars, 1885.)

WE have frequently had occasion to direct our readers' attention to the high-class memoirs which this energetic Society puts forth. The volume before us is one of a kind that we should like to see brought out by our own scientific Societies. Under the title "Niels-Henrik Abel, sa vie et son action scientifique," it contains a full and most valuable sketch, by Prof. C. A. Bjerknes, of Christiania, of the writings and life of one of the ablest and acutest mathematicians of modern times. That the account is a full one will be evident when we say that the work occupies 365 octavo pages: it is a translation in French from the original memoir, and is further enriched by a considerable appendix. The labour of seeing the present form of the work through the press has principally fallen upon M. Houel, to whom the author warmly expresses his thanks. Abel was born at Findö, Christiansand, on August 5, 1802, and died near Arendal on April 6, 1829, and was interred at Froland.

The main body of the work consists of fifteen chapters, and the appendix occupies thirteen chapters more. His works, originally edited by M. Holmboe, the professor under whom he studied, were published in 1839, and quite recently a new edition was referred to in these columns. We give two or three extracts which show the appreciation of his powers amongst his contemporaries, an appreciation which has rather increased than decreased since his death. Jacobi writes of a *deduction* Abel had drawn as being "elle est au-dessus de mes éloges, comme elle est au-dessus de mes travaux." Legendre says, "il me tarde beaucoup de voir les méthodes qui vous ont conduit à de si beaux résultats; je ne sais si je pourrais les comprendre, mais ce qu'il y a de sûr, c'est que je n'ai aucune idée des moyens que vous avez pu employer pour vaincre de pareilles difficultés. Quelle tête que celle d'un jeune Norvégien!" Gauss expresses similar views, and on hearing of Abel's death, wishes for particulars of the life "de cette tête eminenmment distinguée." We could easily add other extracts from Prof. Bjerknes' admirable record of the distinguished Norwegian's life, which is a fitting companion to the before-cited edition of "the works," but forbear. Should any desire, with Gauss, to have his portrait, they will see here in the frontispiece the well-known, to some of us, lineaments.

Solid Geometry. By Percival Frost, D.Sc., F.R.S. Third Edition. (London: Macmillan and Co., 1886.)

IT would have been superfluous to recommend the third edition of Dr. Frost's "Solid Geometry," even if the third edition had been merely a reprint of the second. The book has now taken its position alongside the very best mathematical treatises in use, and requires "no bush." What we have got to do with, however, is no mere reprint: there is once again presented to us a notable increase of matter—much more than a cursory glance is likely to detect—and there has been considerable improvement generally. One change, greatly to the student's advantage, is the careful graduation of the problems at the end of each chapter, and the separation of them into groups. There is still a lack of references to original memoirs, and though, apparently, the author is conscious of it, he needs reminding that it is not sufficient merely to say that this or that is due to Cayley, Chasles, or any one else. Such incomplete statements serve only to give discoverers their dues; they do not assist the advanced and inquiring student.

We have pleasure in learning that an Appendix is about to be issued giving hints for the solution of the problems, but the pleasure is far more than counter-balanced by observing that the title-page bears no longer the words "Vol. I.," the inference being that Dr. Frost has followed the sad example of Thomson and Tait. There is no dearth of men willing and on the whole able enough to write mathematical text-books for beginners: those who could produce a volume to follow Frost's "Solid Geometry" are rare as white crows. When found—by press delegates—they should not only be made a note of, but coerced.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Flora of South Africa

No one, who ever spent much of the impressionable period of his youth at the Cape, that land of lowly plants with exquisite flowers,—but will be vividly interested in the masterly description of those plants' geographical regions of habitat, as given by Mr. Bolus, per your reviewer, "J. D. H.," on pp. 77-79 of your last week's issue.

But what can either one, or other, of those gentlemen mean by saying of "the Natal region" that it is "bounded on the east and south-east by the Atlantic"!

By the Indian Ocean if you like; and then you have a ready means of conveyance for those "Indian types of plants, both in genera and species" which the above-quoted authors say do abound along that eastern coast of South Africa,—but which the Atlantic could never have brought to it.

There is, however, a further local difference in the qualities of the two oceans, of such overwhelming importance to all vegetation, that I wonder no mention appears of it in a Cape botanical essay.

The Natal coast, for instance, on the east, is washed by a warm current from the equator, giving out so much steamy moisture that not only, as your article truly states, are there "the herbage- and bush- and tree-foliage greener, and the leafage larger" than elsewhere; but there, in that region of luxuriously fed, densely growing plants, does game abound; there do Kaffir tribes congregate and establish their kraals; and thereto do Dutch Boers emigrate out of the old, dried-up, southern colony, and found new republics; while therein have we also, every few years, to wage successive wars either with them, or with Zulus or Amakosi tribes of various power, until British lives have been sacrificed by thousands, and British money expended by millions.

But the west coast of South Africa, bless it, being washed by a cold current of the Atlantic coming from Antarctic seas, and giving out little or no vapour, even under a nearly vertical sun, —can hardly but be, even just as it is, an arid desert, where only a few starving Boschjesmen wander miserably up and down, existing perhaps on an occasional antelope, or roasted ants and stray locusts; and no one fights there for permanent possession of the ground.

Now all this egregious contrast between human society, as well as the flora, on the one side, *versus* the other, of Southern Africa (excepting some details dependent on the soil and the prevailing direction of the wind) are due to the Indian Ocean imparting to the air on the east coast an invisible, yet most potent quality which the Atlantic does not confer on the western coast. Could there then be found a more expressive emblazon, suitable to the present day, for a coat of arms for one of the flourishing new Governments on the eastern side of South Africa, than a wet, and dry, bulb hygrometer pictured with both bulbs marking 85° F., and with the surf of the Indian Ocean beating in the distance? The Composition of the Edible Bird's-Nest

As I have been much interested in the controversy concerning the composition of the edible bird's-nest, and particularly in the bearing of Mr. Green's investigations, which are given at length in your last issue (p. 81), would you permit me to give the result of some observations I made on this subject in the Solomon Islands. It will be remembered that it was the association of these nests with a so-called "fungoid growth" in the caves of North Borneo that led Mr. Pryer to consider that he had found the source of the material of which the nests are made, a supposed discovery which led to the re-opening of the controversy (NATURE, vol. xxx. p. 271). This low plant-substance was determined by Mr. George Murray to be the result of the growth of a microscopic alga, a species, probably new, of *Glœocapsa* (*Proc. Zool. Soc.*, 1884, p. 532).

In the Solomon Islands I was only able to obtain the edible nest in one locality (Oima Atoll) since the bird usually frequents inaccessible sea-caves and cliffs. The nests were of inferior quality, and were for the most part composed of fibrous materials derived from the vegetable drift (the husks of pandanus seeds especially). The gelatinous substance thickly incrusted the interior of the nests, and attached them to the rock. The surface of a cliff in the vicinity of the cave frequented by the swifts was coated by a reddish gum-like growth, which proved on examination to be an aggregation of the cells of a protophytic alga about 1/2500 of an inch in size. Unfortunately my specimens of this growth have miscarried, but I feel assured that it is very similar to that observed by Mr. Pryer in the Borneo caves, samples of which, through the kindness of Mr. George Murray, I had the opportunity of seeing at the British Museum. A similar growth is commonly to be found coating the coral-limestone cliffs in this group. It may be seen in all stages, the older portions being dark-coloured and rather tough, and the fresher portions being, as Mr. Pryer aptly remarked, like half-melted gum tragacanth. There are but few cells in the fresh alga, the mass being apparently composed of cellular debris, immersed in a rather diffluent material, the whole somewhat resembling the third section given in Mr. Green's paper.

That the salivary glands are especially concerned in the production of the gelatinous nest-substance there can now be but little doubt, and the investigations of Mr. Green have established the nature of its composition; yet it is possible, and I make the suggestion with great diffidence, that a *vegetable mucin*, or a substance closely allied to this animal product, may be found in these low plant-growths. H. B. GUPPY

"Arithmetic for Schools"

IN NATURE of May 20 (p. 51) there appears a criticism of my "Arithmetic for Schools," in which your reviewer states:—"In the purely arithmetical part of the book logical accuracy is attempted with considerable success. Want of grasp is much more evident in the part which deals with the applications. Then the division into subjects is strangely illogical, and slight inaccuracies of thought and language occur. Is it really the case, for example, that rate of interest (p. 181) is totally independent of *time*?" These are very serious charges to make against a book of the kind, and ought not to be made without very good reason. As your reviewer suggests the inferences (1) that the book is divided into parts, one of which contains the "pure arithmetic," and the other the "applied," and (2) that it is stated that *rate of interest is totally independent of time*, and as neither of these inferences has any foundation in fact, it seems only fair to myself that your reviewer should be asked to quote *verbatim* the other slight inaccuracies on which he bases his general statement.

Gonville and Caius College, May 24 JOHN B. LOCK

SUNSPOTS AND PRICES OF INDIAN FOOD-GRAINS

IN the volume of the *Bombay Gazetteer* which deals with the province of Kathiawar, there is at page 217 a long list of prices of the principal food-grains at Bhavnagar. The list contains, along with other information, the price of Indian millet for nearly every year from 1783 to 1882. This series of figures is long enough to afford the means of testing whether there is any tendency, in India, for times of scarcity, and consequent dearness of food, to recur after more or less regular intervals of years.

Ever since the discovery by Schwabe of the periodicity of the sunspots, and the further discovery by Sabine of the same periodicity in the variations of the earth's magnetism, there has been a growing belief in the minds of scientific men that the varying condition of the sun exerts a far greater influence on terrestrial affairs than is usually thought at all probable, and various investigators have traced, with more or less definiteness, a periodicity of eleven years—coinciding with that of the sunspots—in the variations of the rainfall, in those of the temperature and pressure of the atmosphere, and in the frequency of storms, &c. The late Prof. Stanley Jevons went so far as to express the opinion that even trade depressions are the remote effects of corresponding variations in the condition of the sun.

I am not aware that any attempt has hitherto been made to trace out any direct connection between the variations of prices in India and solar phenomena. The apparent hopelessness of the task has probably acted as a sufficient deterrent, for although it may be reasonable to suppose that solar variations influence the rainfall and other purely physical phenomena, yet it is well known that there are many causes of variation of price which cannot, with any show of reason, be attributed directly to the sun. Such, for instance, are wars, the gradual increase of the population, variations in the quantity of money in use, changes in the total volume of trade, &c. These circumstances complicate the problem very much, but it does not necessarily follow that it is hopeless to attempt to trace the possible influence of solar periodicity on the prices; for there are statistical methods by which most of the disturbing influences can be approximately, if not entirely, eliminated. Indeed, when these methods of elimination have been applied, it may be found that the solar periodicity is more decidedly traceable in the prices than in the rainfall: for, in the one case, the produce of every field exercises its due share of influence in determining the price; while, in the other case, the quantity of rain actually measured is but an infinitesimal portion of the whole quantity which falls, and may therefore very imperfectly represent the total rainfall over the whole of a district.

In considering a price in relation to the causes of variation to which it is subject, it may be thought of as divided into portions, each portion being assigned to its own particular cause. What is wanted here is to separate as distinctly as possible that portion which may be due to the variation of the influence of the sun from all the rest. But before any satisfactory attempt can be made to distinguish that portion of the price variation which may be due to variation of solar influence from the portion due to the average amount of solar influence and to other causes, it is necessary to adopt some standard of comparison which may reasonably be supposed free from solar effects of a periodically variable nature. Now as the physical state of the sun is known to go through a complete cycle of changes in a period of almost exactly eleven years, the average price for any consecutive eleven years

will be affected by the average amount of solar influence, and the difference between this average price and the actual price for the middle year of the eleven will be affected by the difference between the average condition of the sun and its actual condition in that middle year. This difference of price may also include the effects of other extraneous and non-periodic causes. Eleven years after the middle year just mentioned the sun will again be in its former condition, and a similar price difference for that year may be calculated. The same process may be carried on to the twenty-second, thirty-third, &c., years, and it will then produce a series of price differences equally affected by equal periodical solar influence. Non-periodic causes will, however, sometimes tend to unduly raise these price differences, sometimes to depress them, but on the average such disturbances will, in a long series of years, tend to balance each other, leaving the periodical portion of the solar influence outstanding. If, for instance, the years for which the calculations of the price differences have been made are those in which the sunspots are at a maximum, the average price difference will show how much prices tend to be raised or depressed by that condition of the sun which produces most spots. A similar series of calculations may be made for the years in which the spots are at a minimum, also for the intermediate years when the spots are increasing, and for those years when the spots are decreasing. A set of eleven average price differences, one for each year of the sunspot cycle of eleven years, will thus be obtained, and if, on arranging them in consecutive order, they show that prices are, on the average, decidedly high in those years when there are few sunspots, and decidedly low when the sunspots are numerous, or if they show any other decided and systematic variation in the sunspot period, the conclusion will be that the sunspot cycle does really affect the prices. If, on the other hand, the prices do not change in any systematic manner in the different years of the sunspot cycle, the conclusion will be against the hypothesis of a periodical variation of the prices corresponding to the periodical variation of the sunspots.

There is one point of view from which this method of taking differences is open to some objection. Suppose, merely for the sake of illustration, that the average price of millet throughout some particular sunspot period of eleven years is 50 pounds for a rupee, but that in the year of maximum sunspots the solar influence is such as to double the crop and lower the money price or raise the quantity price proportionately, that is, to 100 pounds for a rupee. The price difference for that year would be 50. If, however, by reason, say, of a more plentiful supply of money, the average price of millet for the whole of another sunspot period of eleven years is only 25 pounds for a rupee, and the crop in the year of maximum sunspots is, through solar influence, similarly doubled, the quantity price would only rise to 50 pounds, and the price difference would be only 25, although the solar influence, which is supposed to have produced the change, is the same as before. The difference between the two results would be due simply to the more plentiful supply of money, not at all to a difference of solar influence. This shows that it is needful to adopt some modification of the method, which will allow for gradual changes in the amount of money in use, and other similar causes of alteration of price. Such a modification will be made if, instead of taking price differences, the actual price of the middle year of the eleven is expressed as a percentage of the average price. Expressed in this way, the percentage for the year of maximum sunspots in each of the above examples would be 200, that is to say, in each case the number of pounds for a rupee would be 100 per cent. greater than the average number.

Table I. contains the Bhavnagar price list expressed in the percentage form in the manner just described. In the original table the prices are expressed in pounds for a rupee. If, therefore, the number for any year in Table I. is 125, it means that the number of pounds of grain for a rupee is 25 per cent. greater than the corresponding eleven-yearly average; and if the number is 75 it means that the number of pounds for a rupee is 25 per cent. less. In other words the excess above or the defect below 100 shows how much per cent. the number of pounds for a rupee is above or below the corresponding eleven-yearly average.

TABLE I.—*Percentages, Bhavnagar.*

Years.	1	2	3	4	5	6	7	8	9	10	11
1783 to 1793 . .	57	66	56	143	157	172	185	104	24	60	61
1794 to 1804 . .	66	69	140	163	145	131	108	82	78	75	63
1805 to 1815 . .	70	117	97	139	124	115	106	78	38	69	85
1816 to 1826 . .	118	159	162	103	68	81	78	111	71	51	74
1827 to 1837 . .	141	98	137	96	121	131	135	71	78	79	81
1838 to 1848 . .	91	58	100	92	81	141	164	93	86	107	66
1849 to 1859 . .	132	96	96	102	104	100	106	112	109	84	122
1860 to 1870 . .	103	100	103	86	52	62	87	105	104	92	84
1871 to 1881 . .	93	93	133	126	126	107	89	75	71	89	118
1882	100										
Means, including 1863 to 1866 .	97	95	114	117	109	116	118	92	73	78	84
Means, excluding 1863 to 1866 .	97	95	114	120	116	122	121	92	73	78	84
Smoothed means.	93	100	111	117	118	120	114	94	79	78	86

The numbers of Table I. are arranged in lines of eleven numbers each, so that the numbers occurring at equal intervals of eleven years, beginning with 1783, all fall in the first column, those occurring at equal intervals beginning with 1784, all fall in the second column, and so on. Now if there is any decided tendency for high or low prices to recur at more or less regular intervals of about eleven years, the great majority of the high prices should be found in a few contiguous columns in one part of the table, and the great majority of the low prices in a few contiguous columns in another part of the table. An examination of the numbers of Table I. shows that this is the case, for in columns 9, 10, and 11, no less than twenty-two out of the twenty-seven numbers are below 100, and only five of them are above 100; while in columns 3 to 7 the great majority of the numbers are above 100.

The average results are given at the foot of the table. They show that there is a decided tendency for years of high and low prices to recur, with some regularity, in a period of eleven years, five consecutive years being good years, when money prices are below the average; and the six following years being bad years, when money prices are above the average. The years which give the highest average money price, or the smallest number of pounds for a rupee, are those in column 9. The average number of pounds for a rupee in those years is 27 per cent. below the eleven-yearly average. The years which give the lowest average money prices are those in columns 4, 6, and 7. The average number of pounds for a rupee in those years is about 17 per cent. greater than the eleven-yearly average. There is thus an average difference of 44 per cent. between the years of low prices and those of high prices. This percentage difference would have been considerably greater if the prices had been reckoned in rupees for a fixed quantity of grain, instead of in pounds of grain for a rupee. To show that this is the case it is only necessary to convert the three prices 117, 100, and 73 regarded as pounds for a rupee, into their corresponding rupee prices, that is to say, into the number of rupees which would in each case be required to purchase 100 pounds. These are 0·85, 1·00, and 1·37 respectively,

giving a difference between the highest and lowest of 0·52, or no less than 52 per cent. of the average price, which is 8 per cent. more than the corresponding difference in the pound prices. Although this illustration by no means exhausts the question of the difference between quantity prices and money prices, it suffices for the purpose of guarding against the erroneous supposition that results worked out in quantity prices are directly applicable to money prices.

Having now found such remarkable evidence of regularly recurring periodical variations of the price of the staple food-grain at Bhavnagar, amounting on the average to more than 50 per cent. of the average money price, it seems desirable to inquire whether similar variations of price have taken place from year to year in other districts. For this purpose I have selected from the various volumes of the *Bombay Gazetteer* all those price lists which extend over periods of fifty years or more. These are for the districts of Ahmedabad, Kaira, Surat, Khandesh, Poona, Bijapur, Dharwar, Belgaum, and Kanara, and to these I have added Madras, for which station a long price list is given in the Report of the Indian Famine Commission.

The best way of testing whether any considerable portion of the variations of price in these districts can be regarded as regularly recurrent in a period of eleven years, corresponding to that of the sunspots, is to calculate the average eleven-yearly variation by the method already applied to the Bhavnagar prices. These calculations have been made. The results are entered in Table II. The corresponding average sunspot variation is also given.

TABLE II.

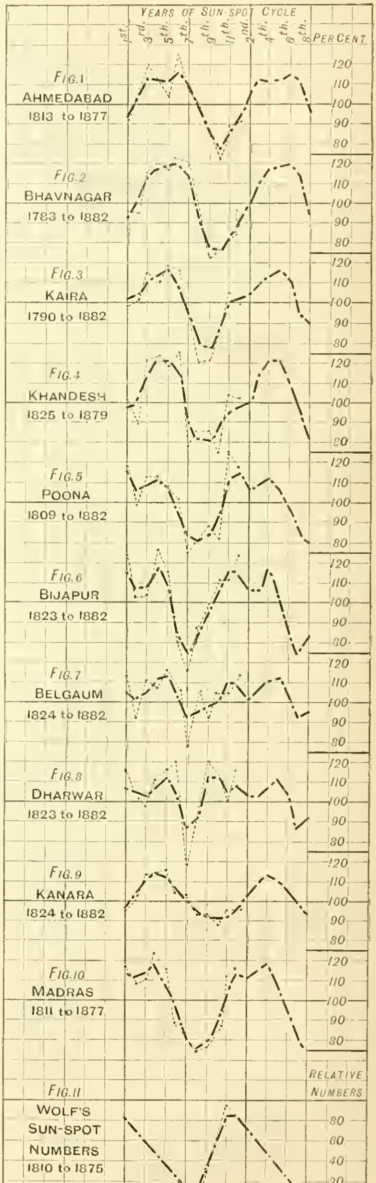
In calculating the average sunspot variation the sunspot numbers before 1811 have been excluded, partly because they are very much less reliable than the numbers for the later years, from lack of continuous observations, partly because the mean variation for the later years will be more directly comparable with the price variations, which, except in two cases, are deduced from the data of the years following 1810. In calculating the average eleven-yearly price variations the data for the years 1863 to 1866 have been excluded, because it is known that in those years prices were very much raised by the influence of the American war.

There is some irregularity in the eleven-yearly price variations (especially in those for Dharwar and Belgaum) which can hardly be attributed directly to the solar influence. The best way of removing this irregularity will be to take the means of each consecutive pair of the eleven

[1] The year 1871 is taken as the first year of the sunspot cycle of eleven

PRICES OF FOOD GRAINS IN INDIA
RECKONED IN POUNDS FOR A RUPEE.



average numbers which constitute the eleven-yearly price variation, and to repeat the process on the new means. This has been done, and the results are given in Table III.

These smoothed results are graphically represented by the dots connected with black lines in Figs. 1 to 10. To show the effect of the smoothing process the original unsmoothed numbers, viz. those of Table II., are graphically exhibited over the smoothed curves by the dots joined with faint dotted lines. It will be seen from these figures that the application of the smoothing process has got rid of almost all the irregularity. At the same time it has somewhat unduly reduced the range of the eleven-yearly variations. The amount of this reduction may be roughly estimated by applying the same smoothing process to the eleven average sunspot numbers given in the last column of Table II. This has been done in the last column of Table III. The results are curved in Fig. 11. The range of the original unsmoothed numbers is 82·9, that of the resulting smoothed numbers is 70·6; that is to say, the range of the smoothed numbers would have to be increased by 17 per cent. of itself to obtain the full range of the original numbers. From this it may be inferred that the range of each of the smoothed eleven-yearly price variations represented by Figs. 1 to 10 is too small, and should be increased by about 17 per cent. of itself to obtain the full range of the variation. On the other hand, the extreme range of the unsmoothed numbers will probably be somewhat too great in most cases, because the data do not extend over a sufficient number of years to eliminate completely the effects of casual fluctuations. The true mean range of the variation caused by solar influence will therefore probably lie somewhere between the range of the unsmoothed numbers and that of the smoothed numbers. The ranges of both the unsmoothed and the smoothed variations are shown below for each district. The range of each smoothed variation increased by 17 per cent. of itself is also given.

Now these results reveal the remarkable fact that, amid all the apparently irregular fluctuations of the yearly prices, there is in every one of the ten districts a periodical rise and fall of prices once every eleven years, corresponding to the regular variation which takes place in the number of the sunspots during the same period. They also show that in seven out of the ten districts the range of the eleven-yearly variation of prices lies between 40 and 50 per cent. of the average price, and that in the remaining three districts the range lies between 20 and 30 per cent. The ranges are greatest in those districts where scarcity and famine are most frequent, smallest in those which enjoy the greatest immunity in these respects. In Bijapur and the neighbouring districts of Belgaum and Dharwar the highest prices occur in the year of minimum sunspots; in Madras, Poona, and Khandesh a year or two later; in Kanara, Kaira, and Bhavnagar two or three years later; and in Ahmedabad three years later. The lowest prices occur in all the districts from three to five years after the year of maximum sunspots, that is to say, three years after at the southern stations; four or five years after at the northern. Bijapur and Poona are the first to show a very decided rise of prices, and this rise takes place in the year preceding the year of minimum sunspots. At all the other stations a very decided rise takes place a year or two later.

From what has been said it follows that the intervals of time between the year of minimum sunspots and the years of highest prices are less than the intervals between the year of maximum sunspots and the years of lowest prices. This shows that the eleven-yearly price variations do not exactly correspond to the eleven-yearly sunspot variation. The reason may be that on the occurrence of scarcity prices rise very rapidly, while on the return of a season of plenty they fall much more slowly, because the reserve stocks of grain consumed during a period of scarcity cannot be fully replaced until good crops for several successive years have been secured. If it were possible to obtain data showing the actual out-turn of the crops of each year, it would perhaps be found that the eleven-yearly variations calculated therefrom would correspond to the sunspot variation even more closely than the price variations correspond to it.

In estimating the significance of these eleven-yearly variations it must be remembered that quantity prices, not money prices, have been dealt with, and that the corresponding money prices would show a much greater percentage rise in dear times, and a less percentage fall in cheap times than are shown by the quantity prices. Indeed, to a person accustomed to thinking of money prices the quantity prices are apt to be very misleading if the difference is not constantly borne in mind, as may be seen from the consideration that if the quantity price, that is, the number of pounds for a rupee, becomes 50 per cent. less, that is dearer, than usual, the corresponding money price is 100 per cent. higher; while if the quantity price becomes 50 per cent. more, that is cheaper, the corresponding money price is only 33 per cent. lower. From a money point of view, therefore, a fall of 50 per cent. in the number of pounds for a rupee is much more serious than it seems to be, while a rise of 50 per cent. in that number is less advantageous than might at first sight be supposed. For financial purposes it would probably be best to convert the quantity prices at the beginning into their money equivalents, because it is impossible accurately to convert results (such as averages and the like) worked out in quantity prices into corresponding results, expressed in money prices.[1] Such conversions always give a too favourable appearance as regards cheap-

[1] For purely scientific purposes it would perhaps be best to work with the logarithms of the original prices, instead of with the prices themselves, regardless as to whether the prices are expressed in pounds for a rupee, or in rupees for a fixed quantity of grain. It would then be possible to pass directly from the results of one system to those of the other, without having to go through the labour of recalculation.

ness of food in times of plenty; and make the dearness of food in times of scarcity appear far less serious than it really is.

One of the most important practical results of this investigation probably is, that it affords a certain amount of power to predict the variations of prices in the coming sunspot cycle. Of course, until all those fluctuations which appear at present to be subject to no law have been explained and reduced to order, if ever that should be possible, exact prediction in any individual case is altogether out of the question, but as there is a regularly recurring eleven-yearly wave of prices running through the irregular fluctuations and following the sunspot wave in the manner defined by the curves, it is possible to form an estimate of the general level of prices in the different years of the coming sunspot cycle. There is thus some reason for believing that the present period of low prices following the last maximum of sunspots, which appears to have occurred about the end of 1882 or early in 1883, will not last very much longer, a brisk rise of prices being due in the Deccan and in Madras five years after the sunspot maximum, that is, in 1887 or 1888, and in more northern districts a year or two later.

This estimate will, of course, be subject to modification if it should be found that the sunspot curve is declining towards its minimum more or less rapidly than usual. The last period of sunspots appears to have been somewhat longer than the average, that is, about twelve years from the maximum of 1870 to that of 1882, instead of the normal length of almost exactly eleven years; and the coming minimum may possibly follow the last maximum more quickly than usual. Fortunately, the sunspot observations are not the only indicators of this cosmical periodicity, for, as I have shown in a paper communicated to the Royal Society in 1884, the magnetic observations recorded at the Colaba Observatory afford far smoother and more definite indications of this periodicity than the sunspot observations; and, what is even more important, the eleven-yearly magnetic variation precedes the sunspot variation by almost exactly six months, so that the magnetic indications are given half a year earlier than those of the sunspots. FREDERICK CHAMBERS

Bombay, April 1886

THE PHYSICAL APPEARANCE OF MARS IN 1886

A SERIES of observations of Mars were obtained here in March and April last with a 10-inch silver-on-glass reflector by With of Hereford. The powers employed were 252 and 475, but I found no advantage from the latter, which seemed too high for the purpose. As a rule a single lens magnifying 252 was amply sufficient, though there were several occasions when a power of about 350 would have been a decided acquisition.

The planet came to opposition on March 6, but during the first three weeks of March we had intense frosts, and it was not feasible to commence observations until towards the end of that month. The opposition magnitude of Mars was only 16″·6, so that as regards apparent diameter the planet was far from being favourably placed. At the opposition of 1877 the diameter was no less than 29″·5. But at the recent opposition the north hemisphere of the planet (which has not hitherto been so thoroughly examined as the south hemisphere, and does not exhibit so many striking features) was well presented for observation, the latitude of the centre of the disk being about 22° N. in March and April.

The markings seen were both numerous and diversified. There is evidently a mass of detail on the planet, which is, however, most difficult to trace out in reliable characters. Many faint lineaments reach the eye with sufficient distinctness to prove their existence, but they cannot be held steadily enough or with that perspicuity to allow of the delineation of their outlines, or to enable their relative positions to be correctly assigned. Only the more pronounced features can be drawn satisfactorily. The small diameter of Mars during the recent observations has in a great measure induced this uncertainty as to the physical aspect of the disk. Another cause is found in the rarity of really good telescopic images. Not only must the atmosphere be peculiarly favourable to sharp definition, but there must be an absence of wind. A complicated system of markings cannot be made out under the influence of annoying vibrations. Moreover, this planet, considered as a telescopic object, is far less satisfactory than either Jupiter or Saturn, and this circumstance, with the other drawbacks alluded to, have given rise to that uncertainty, and to many of the discordances, in regard to the visible markings observed on his surface.

My intention in the present paper is merely to describe general results, as a particular description would scarcely be intelligible without drawings. Between March 23 and April 30 the planet was examined on twenty-one evenings, and a considerable number of sketches were completed. During the period mentioned the weather afforded an unusual number of clear nights, and whenever the seeing was fairly good the visible features were carefully noted, the results being afterwards compared with each other and with former work in the same direction. My drawings correspond very closely amongst themselves, and there is a fair agreement in the main features with those depicted on the charts of Green, Schiaparelli, Knobel, and others. I have also compared them with the views given in Terby's work on Mars and with Boeddicker's drawings of 1881 and 1884 (with Lord Rosse's 3-foot reflector) published in the scientific *Transactions* of the Royal Dublin Society, and find in many instances a substantial confirmation. Some of the differences are larger than would have been considered probable, but experience has taught us that it is useless to expect uniformity in delineations of planetary details.

During the five weeks over which my observations extended I saw no conclusive evidences of physical changes in any of the markings. But the period was too limited, and the circumstances affecting the review altogether too unfavourable, to enable me to speak definitely on this point. The slight differences apparent amongst my drawings are merely such as were occasioned by changes in local atmospheric conditions. On a bad night faint markings, previously distinguished, would appear obliterated, and on thoroughly good nights I saw delicate appearances which were utterly beyond reach on less auspicious occasions. I am convinced that these changes in the character of the seeing, exercise great influence on the distinguishable features of a planet; more so, in fact, than observers usually concede. Inferences of real change are sometimes hastily adopted in consequence, but they can only be substantiated after the most searching examination and the most convincing proofs.

The exterior edges of many of the well-defined seas on Mars are very brilliant, and their boundaries very definite. These brilliant outlying borders remind one of the light areas often abutting on the dark spots of Jupiter, only in the case of Mars they are more extensive, more permanent, and altogether dissimilar in form. I may instance a particular case of this bright bordering in the immediate region east of the Kaiser Sea on Mars. On several occasions this was so striking as to vie with the bright patch about the north pole. This shimmering extends several degrees east of the dark outline of the sea, but is limited by a faint and irregularly-condensed marking extending northwards, with an inclination east, from the knot in longitude 290° just east of the north extremity of the Kaiser Sea as figured in Mr. Green's chart. This marking runs over a considerable tract, and its east extension underlies Davies' forked bay and Burton Bay, to both of which it is connected by faint ligaments of shade,

reminding one of the "canals" of Schiaparelli. This special marking, which is not included in Mr. Green's map, may be identical with the network of dark narrow streaks figured in this region by Schiaparelli in his chart for January and February, 1882. It is also more or less definitely shown in some other drawings, notably on one by Schmidt, which forms No. 17 in Dr. Terby's Areography.

As to the Kaiser Sea, it appears very faint and narrow, if not really broken, in the region some 10° or 15° south of its north extremity. This peculiarity is well drawn in Herr Boeddicker's drawings of December 27, November 19, and December 26, 1881 (Nos. 11, 13, and 14) in the scientific *Transactions* of the Royal Dublin Society for December, 1882. Consulting other drawings I cannot find that this feature is sufficiently indicated. It is obvious, however, that it would only be well detected when placed near the apparent centre of the disk as during the recent opposition.

Mr. Knobel's drawings in 1873 (*Monthly Notices*, vol. xxxiii., facing p. 476) agree generally with mine far closer than those he has published in the *Memoirs*, vol. xlviii. part ii., 1884. I always see Knobel Sea on Green's chart separated on its south side from the fainter curving band running east, as in the sketches Nos. 6, 7, 8, and 9, 1873. This break is not depicted in the subsequent drawings of 1884, so that the appearance has either been subject to actual variation of aspect or the difference of inclination has originated the want of uniformity. Probably the latter is the real cause, for the inclination of Mars in April and May, 1873, was nearly identical with that of March and April, 1886, and it is for these periods the drawings are so nearly alike in their more conspicuous forms. I see the northern boundary of Knobel Sea distinctly separate from the dark longitudinal strip immediately contiguous to the north polar cap. The drawing No. 12, May 19, 1873, by Mr. Knobel, portrays the leading features of this region much as I have more recently observed them. In 1884, Mr. Knobel delineated the whole mass of shading outlying the north pole as blended uninterruptedly, but these differences are unquestionably due to the changes of inclination, which must necessarily introduce such discordances into the apparent forms of the markings as observed at different epochs.

As to the canal-shaped features of Schiaparelli, first seen in 1877 and 1878, and subsequently confirmed, I have distinguished a large number of appearances highly suggestive of such a configuration, but the Italian drawings made during the three months from October, 1881, to February, 1882, give them a definite character, and (apart from their duplication) a straightness of direction and general uniformity of tone which my observations do not confirm. The more delicate and complex markings on the planet appear to my eye, under the best circumstances, as extremely faint, linear shadings with evident gradations in tone and irregularities occasioning breaks and condensations here and there. If they existed under the same aspect and with the same boldness as delineated by Schiaparelli, they would have been readily detected here whenever the seeing was fairly good, for these objects are referred to as readily observed in the 8-inch refractor of the Milan Observatory in February, 1882, when the planet's diameter was only 13″. The duplication of these lines was also traceable under the same unfavourable conditions. The wonder is, not that the eminent Italian astronomer has discovered such a marvellous extent of curious detail on this planet, because this detail unquestionably exists, though scarcely in the form and character under which it is represented, but that he should have observed its more complex and difficult configuration at the very period when Mars was so very unfavourably situated for observations of this critical nature.

The surface markings of this planet are so numerous and varied that they are far from being adequately represented on existing charts. In certain regions the disk is so variegated as to give a mottled appearance. Dark lines, and spots, and bright spaces are so thickly interspersed, and so difficult to observe with sufficient steadiness to estimate their positions and forms, that I found it impossible to make thoroughly satisfactory drawings. An observer has to be content with endeavours to depict the more prominent marks only, and even in connection with these there is always some element of uncertainty. The rotation-period of the planet is, however, so slow, the hourly rate being only 14°·6 in comparison with 36°·7 in the case of Jupiter, that plenty of time is afforded for drawing the leading markings before they show a displacement obvious to the eye. In addition to this a drawing of Mars may be made to rest on several successive evenings of observation if the observer comes 37·4 min. later to the telescope on each occasion. In regard to Jupiter the difficulty of suitably drawing the details is far greater, though they admit of more ready observation. The rapid rotation of this planet displaces objects in a few minutes, and makes it imperative that the work both of observing and charting should be very hastily performed; and it is not feasible in this case to base a sketch on observations of following nights, because the markings are influenced by different velocities, and suffer large relative displacements even at short intervals of time.

During the past few months the north polar cap of Mars has been very bright, sometimes offering a startling contrast to those regions of the surface more feebly reflective. Some of the other parts were also notably brilliant. These luminous regions of Mars require at least as much careful investigation as the darker parts, for it is probably in connection with them that physical changes (if at present operating on the planet's surface) may be definitely observed. In many previous drawings and descriptions of Mars sufficient weight has not been accorded to these white spots.

Many of our leading treatises on astronomy attribute a dense atmosphere to Mars, but nothing has been observed during my recent observations to corroborate this theory. It seems to me far more plausible to assume that the atmosphere of this planet is extremely attenuated. The chief spots are invariably visible, and the phenomena occasionally observed are rather to be imputed to the vagaries of our own atmosphere than to that of Mars. Jupiter and Saturn are doubtless enveloped in dense vapours shrouding their real surfaces from terrestrial eyes. Their markings are atmospheric, though in some cases very durable, and constantly undergoing changes of aspect and displacements of position by longitudinal currents. On Mars a totally different nature of things prevails. Here the appearances descried are absolute surface markings displaying none of the variations which are so conspicuously displayed in the markings on Jupiter. It is probable that many, if not all, the changes supposed to have occurred in the features of Mars are simply attributable to the constantly varying conditions under which the planet has necessarily to be observed. Were the circumstances of observation more equable there would be much greater unanimity amongst observers of this interesting object. It seems to me that the very pronounced character of the markings and their great permanency are quite opposed to the idea that the planet is surrounded by a dense cloud-laden atmosphere.

W. F. DENNING

M. CORNU ON THE HYDROGEN FUNCTION OF CERTAIN METALS[1]

WHEN we examine on different photographs those groups of lines which reappear periodically with a particular regularity, we find that these groups belong

[1] Translation from an article in the *Journal de Physique*.

precisely to the category of those which reverse themselves; for some are reversed and the others are on the point of being so. For the same metals, the reversals are more or less complete according to the conditions of the experiment, and for different metals according to their chemical and physical properties.

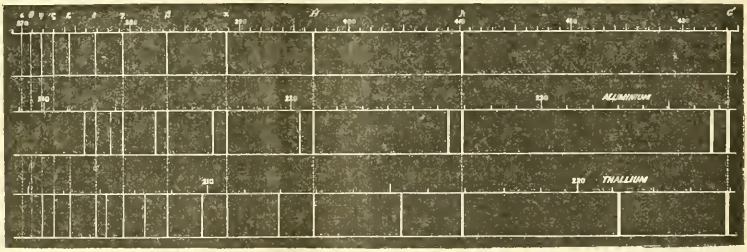
The law of distribution of these groups presents another common character relatively to the succession of distances and intensities: the lines get nearer together towards the more refrangible end and diminish in intensity. This character is much the more striking when the number of reversed lines is considerable, because the field on which they appear is more uniform. It seems that with the elevation of temperature the spectrum tends towards a limit, that of a continuous brilliant background despoiled of all lines except the regular series of the self reversing ones. It is to this constitution that I wish to draw the attention of observers.

The number of metallic spectra capable of giving a regular series of spontaneously reversed lines on a continuous background is considerable; but the most beautiful series that I have observed were supplied by two metals which one could scarcely have anticipated, from a chemical point of view, to find side by side; these are aluminium and thallium, whose equivalents are at the extremity of the list of those of the simple bodies. The diagram gives an idea of the distribution of these reversed lines; one sees that they form in each spectrum a series of doublets fulfilling the conditions of distance and intensity given above.

I shall not stop to indicate the fruitless trials of numerical calculations that I have taken in hand in order to represent each of these series by the substitution of the series of entire numbers in a simple function; I may add that I had given up these researches until the discovery of Dr. Huggins on the spectra of white stars brought back my attention to this subject.

These spectra present, in fact, a common series of dark lines, that is to say, reversed, fulfilling precisely the conditions of distance and intensity which characterise in metallic spectra the spontaneously reversed lines: they prolong the series of well-known lines of the spectrum of hydrogen, C, F, G, *h*. One could then foresee that the whole series belonged to them; that is what has since been confirmed by Vogel, though this result is still not quite certain. The interest of this identification was such that I sought to prove it myself, which I could not realise till lately. The experiment is not without difficulty; but in taking more minute precautions to get rid of all impurity in the hydrogen, I have seen the impurity lines obliterated, and finally I succeeded in obtaining photographs showing the series of star-lines in all their purity.

The spectrum of hydrogen is placed on the first line in the above diagram: the comparison has been rendered easier by the choice of scales showing intuitively the identity of the law of distribution of lines in the three spectra.



DESCRIPTION OF THE DIAGRAM – The graduations define the lines according to their wave-lengths. The first line represents the dark lines of the violet and ultra-violet spectra of the white stars. The second represents a double series of inverted lines in the ultra-violet spectrum of aluminium (electric arc). The scale of the drawing has been chosen in a manner to make G and δ coincide with the homologous lines of the first series (first line of each doublet). One could have operated in the same way with the second series (second lines). This mode of representation advantageously replaces the numerical tables, showing the verification of the two empiric formulas—

First series ... ... $\lambda_1 = 47\cdot30 + 0\cdot43783\, h$
Second series ... ... $\lambda_2 = 47\cdot18 + 0\cdot43678\, h$

which give the length of the wave of each line in function of the wave-length h of the corresponding line of hydrogen; the difference between the calculation and the observation is of the order of the experimental errors. The third line represents a double series of inverted lines in the ultra-violet spectrum of thallium (electric arc). The scale of the drawing was chosen like the one above; the empiric formulas which represent these two series are:—

$$\lambda_1 = 94\cdot61 + 0\cdot29776\, h$$
$$\lambda_2 = 111\cdot31 + 0\cdot75294\, h.$$

We might compare in the same way the more complex groups, like magnesium, zinc, sodium, &c.; the only difficulty is to establish the agreement of the groups; we do this immediately by a quite simple graphic construction. We arrive at the following statement, which resumes the whole of my researches. In the metallic spectra certain series of lines, spontaneously reversed, present sensibly the same law of distribution and intensity as that of the hydrogen lines.

It is not necessary to dwell on the importance of this relation: it makes evident the existence of a law which is general relatively to the emissive powers of incandescent vapours, and, again, it shows that this law of succession of spectral lines, common to so many series, seems to be expressed by the help of the same function, which one might call the hydrogenic function, which should play the principal part in these studies: the result then appears to constitute a first step towards the solution of the great problems which the spectroscope brings on for solution.

R.

VEGETATION OF SOUTH GEORGIA

ON Tuesday, January 17, 1775, Capt. Cook landed on this remote island, which is situated about 1000 miles east of Cape Horn, in about 54° S. lat. and 37° W. long., and took possession of it in the name of King George the Third, after whom he named it. Capt. Cook landed in three different places, and the ceremony of adding the island to the British dominions, he informs us, was performed under a waving of colours and a discharge of small arms. Whether any British subject has ever set foot on it since that day I know not; but the description of the island by its famous discoverer was not likely to tempt any one to go out of his way with that object in view. Although

lying only as far south of the equator as York is north of it, South Georgia is covered, in the higher parts at least, with permanent snows and glaciers, and is altogether of a most wild and desolate aspect. Large masses of ice were continually breaking off from the perpendicular cliffs and falling into the sea with a noise like cannon. "The inner parts of the country," says Cook, "were not less savage and horrible. The wild rocks raised their lofty summits till they were lost in the clouds, and the valleys lay covered with everlasting snow. Not a tree was to be seen, nor a shrub even big enough to make a toothpick. The only vegetation we met with was a coarse strong-bladed grass growing in tufts, wild burnet, and a plant like moss, which sprung from the rocks."

Animal life, however, was more abundant. Seals were plentiful, and the penguins the largest ever seen by Cook; some which were taken on board weighed from twenty-nine to thirty-eight pounds. Eight kinds of "oceanic birds" are enumerated, and one, a yellow bird, was found to be delicious food. All the land birds observed were "a few small larks." From Cook's narrative it appears that Forster, the botanist, was one of the landing party, hence it might have been expected that few flowering plants would have escaped observation, especially as the visit was made in January, the midsummer of the southern hemisphere. Forster himself states ("Observations made during a Voyage round the World," p. 16) that South Georgia is an isle of about eighty leagues in extent, consisting of high hills, none of which were free from snow in the middle of January, except a few rocks near the sea. And he adds that there was no soil except in a few crevices of the rocks.

No further information respecting this island has been published, so far as I am aware, until since the return of a recent German Expedition, which made the island one of its stations for meteorological and other observations. When collecting the materials to illustrate the flora of the very much broken coldest southern zone of vegetation for the "Botany of the *Challenger* Expedition," I had to be content with Cook and Forster's very meagre accounts of South Georgia; but from the published northern limits of drift ice in different longitudes in the southern hemisphere, it was not expected that South Georgia possessed much more than the scanty flora they attributed to it, though Macquarie Island, in the same latitude, and nearly in the longitude of New Zealand, was known to support a comparatively luxuriant vegetation. Dreary and barren as it is, however, South Georgia is not so bad as it has been painted. The officers of the German Expedition spent nearly a year on the island, and appear to have explored it thoroughly, botanically and otherwise. During this period the atmospheric pressure was subject to extraordinary fluctuations, the extremes exhibiting a difference of 64 millimetres, or a fraction over $2\frac{1}{2}$ inches, while the range of temperature during the same period was only 48·6 Fahr., or in round numbers, from 8° to 57° Fahr.; thus showing the freezing-point to be nearly midway in the range. The actual mean temperature of the year was 35°·06 Fahr.; of June, the coldest month, 25°·6 Fahr.; and of February, the warmest month, 41°·6 Fahr.

With regard to the flowering plants collected in the island by Dr. Will, one of the officers of the Expedition, we are indebted to Dr. Engler for an enumeration of them in his *Jahrbücher*, vol. vii. p. 281. They are thirteen in number, and their general distribution is so extremely interesting that I may be pardoned for giving it in detail:—

(1) *Ranunculus biternatus*, Sm. (Ranunculaceæ).—Fuegia, Falklands, Tristan d'Acunha (?) Marion, and Kerguelen Islands.

(2) *Colobanthus subulatus*, d'Urville (Caryophyllaceæ).—Fuegia, Campbell's Island, New Zealand, and Alps of Victoria, Australia.

(3) *Colobanthus crassifolius*, d'Urville (Caryophyllaceæ).—Fuegia and Falklands.

(4) *Montia fontana*, L. (Portulaceæ).—Fuegia, Marion, Kerguelen, Campbell's Island, and widely diffused.

(5) *Acæna adscendens*, Vahl. (Rosaceæ).—Fuegia, Marion, Crozets, Kerguelen, Macquarie Islands, and New Zealand.

(6) *Acæna lævigata*, Ait. (Rosaceæ).—Fuegia.

(7) *Callitriche verna*, L. var. (Halorageæ).—Fuegia, Marion, Kerguelen, Heard Islands, New Zealand, and widely diffused.

(8) *Juncus novæ-zealandiæ*, Hook. f. (Juncaceæ).—New Zealand.

(9) *Rostkovia magellanica*, Hook. f. (Juncaceæ).—Andes, Fuegia, Falklands, and Campbell's Islands.

(10) *Aira antarctica*, Hook. f. (Gramineæ).—Fuegia, Falklands, South Shetlands, and Kerguelen Island.

(11) *Phleum alpinum*, L. (Gramineæ).—Magellan's Straits, and widely dispersed in the cold regions of the northern hemisphere.

(12) *Festuca erecta*, D'Urville (Gramineæ).—Fuegia, Falklands, and Kerguelen.

(13) *Poa flabellata*, Hook. f., syn. *Dactylis cæspitosa*, Forst. (Gramineæ).—Fuegia and Falklands.

From the collector's remarks, appended by Engler to each species, it appears that some of the foregoing plants flourish luxuriantly in South Georgia, especially the species of *Acæna* (the burnet of Cook's narrative), and *Aira antarctica* and *Poa flabellata*. The *Ranunculus* was abundant by the side of a stream and elsewhere, and *Colobanthus subulatus* (doubtless the moss-like plant mentioned by Cook) formed large tufts on the south side of the hills. Nine out of the thirteen plants in South Georgia are also found in the eastern part of this southernmost zone of vegetation from Kerguelen to New Zealand, taking these islands together. One, *Juncus novæ-zealandiæ*, had not previously been found in what may be termed the American part of the zone; but, as Prof. Buchanan, to whom Dr. Engler submitted the South Georgian specimens, remarks, this is so nearly allied to the South American *Juncus stipulatus* that it may be cited as another instance of representative and closely-allied species in the American and Australian regions.

Thus are we gradually obtaining a knowledge of the vegetation of the detached fragments of the Antarctic flora; yet several islands are still quite unknown botanically or only very imperfectly. Concerning Diego Alvarez, or Gough Island, situated about 4° south of the Tristan d'Acunha group, we know nothing except that the vegetation is said to be similar to that of Tristan d'Acunha, and to include *Phylica nitida*, the only arboreous member of the latter flora. Then there is a group of islands, including Lindsay, Bouvet, and Thomson, in about the same latitude as South Georgia, but 35° eastward, of which nothing is known botanically.

W. BOTTING HEMSLEY

NOTES

THE Visitation of Greenwich Observatory takes place on Saturday next.

THE Ladies' *Soirée* at the Royal Society takes place on the evening of Wednesday, the 9th inst.

THE honour of C.M.G. has been conferred on Mr. Charles Meldrum, Director of the Royal Alfred Observatory, Mauritius.

THE explosion of the 43-ton gun has led to the appointment of a Committee of Inquiry, in which the name of Mr. Anderson is conspicuous by its absence, although surely no greater authority on the points at issue exists. A year ago, in his important lectures at the Society of Arts, he drew attention to the want of relation between the sections and pressures, and predicted disasters.

Sir Bernhard Samuelson, M.P., and Mr. Philip Magnus, of the City Guilds of London Institute, have been appointed by the Education Department English representatives at the International Congress on Technical Education, to be held at Bordeaux in September next.

Prof. Flower, the Director of the Natural History Department of the British Museum, has allowed the zoological collections made by Brigade-Surgeon J. E. T. Aitchison, C.I.E., the naturalist lately attached to the Afghan Delimitation Commission, to be placed on view temporarily at the South Kensington Department. To those interested in the zoology of those regions and in the geographical range of species, a view of these collections in their entirety will be found most interesting. We believe that at an early date this collection will be broken up to be sent to India, and distributed to various museums and countries, and that it is only localised here until such time as a report on its details is furnished to the Government of India.

Mr. Nicholson has been appointed Curator of Kew Gardens, in the room of Mr. Smith, resigned. Mr. Nicholson has been one of the chief assistants at the Gardens for some years.

A series of Conferences on the "Mineral Resources of the Colonies and India" will be held by the Geologists' Association in the Colonial and Indian Exhibition on Saturday afternoons, commencing at 3 p.m. After the reading of the paper there will be a discussion, terminating at 4.30. The Conference will then adjourn to the Courts, where further explanations of the exhibits will be given. The first meeting will be on Saturday next, when an address will be given on the Mineral Resources of India and Burmah, by Prof. V. Ball, F.R.S.; Sir Richard Temple will preside. The arrangements for succeeding Saturdays are as follow:—June 19, South Africa, by Prof. T. R. Jones, F.R.S.; Sir Ch. Mills in the chair. July 3, Canada, by Dr. A. R. Selwyn; the Marquis of Lorne in the chair. July 17, New Zealand, by Dr. J. Von Haast. July 24, Australia, by Mr. F. W. Rudler. There will probably also be a lecture by the President of the Geologists' Association (Mr. W. Topley), on the Coaling Stations in Relation to the Fuel Deposits of the Empire; but the date of this is not yet fixed. Conferences of the Anthropological Institute on the Races of the British Empire will also be held in the Conference Hall of the Colonial and Indian Exhibition. The first was on Tuesday on the Races of Africa. The others are:—Monday, June 7: Races of America (West Indies). Tuesday, June 22: Races of Australia. Tuesday, June 29: Races of New Zealand, Fiji. Tuesday, July 6: Races (Aboriginal) of India. Tuesday, July 13: Races of Ceylon, Straits Settlements, Borneo. The chair will be taken at 4 p.m. The memoirs read and discussed in the Conference Hall will be illustrated by selections from the exhibits. Afterwards, but not later than 5 o'clock, the Conference will adjourn to the Courts, and there inspect and hear explanations of the remaining exhibits connected with the subject of the day.

The Lick Trustees have decided to purchase from Messrs. Feil and Mantois a 36-inch crown disk, which was made by them at the same time with the crown disk of the objective now in the hands of the Clarks. The Clarks "have received the order to figure this disk as a third (photographic) lens for the large objective."

A curious phenomenon, the *Scotsman* reports, was witnessed at Stonehaven on Sunday afternoon, May 23. At intervals, just before and after high tide, without any apparent cause, the water along the coast rose and fell from 10 to 18 inches at a time, the subsidence leaving as much as 15 to 18 feet of the beach dry. The disturbance continued for three hours, commencing at about half-past 4 o'clock. There was no wind, and the sea was quite smooth, but the water advanced and retired with a speed equal to the run of a large river during a spate, and caused so much commotion in the harbour that the fishermen had to secure their boats with extra moorings to prevent damage being done. Indeed, it is seldom that there is so much commotion in the harbour, even during stormy weather. It is surmised that the phenomenon was due to some eruption or subsidence in the sea bottom.

The Executive Committee of Aberdare Hall, Cardiff, has issued a most satisfactory report of the progress of Aberdare Hall during its first term. Seven students were entered when this Hall for lady students was opened in October 1885. Two of these are studying for the Intermediate Science Examination (London University), one for the Intermediate in Arts, and four for the Matriculation Examination. Two scholarships tenable at Aberdare Hall were awarded. At the beginning of the next session several large scholarships and many exhibitions will be offered for competition at University College, Cardiff, and three exhibitions tenable at Aberdare Hall. The institution deserves every encouragement.

The New York Assembly has passed the Bill providing for the appropriation of 20,000 dollars annually to the Metropolitan Museum of Art and the American Museum of Natural History, in order that they may be kept open to the public, free of charge, on Sundays. It is expected that it will soon be favourably reported by the Senate Committee, and become law.

Up to Saturday morning the accounts from Catania were reassuring; the flow of lava was much slower and was rapidly cooling, and Nicolosi was considered almost safe. But at 4 p.m. a fresh outpour of lava manifested itself, and flowing over the earlier stream which had partially hardened, it again menaces Nicolosi and Belpasso. At 9.15 p.m., the lava stream which threatens Nicolosi showed a front 180 metres wide, from 6 to 10 metres high, and was moving at the rate of 10 metres per hour. According to latest reports the eruption is as active as ever.

On April 28 a lovely mirage was seen at about noon at Östersund, in Northern Sweden. In the south-west, above the Storsjö, a great lake, the lofty Oviks Mountains, covered with snow, were seen reflected on the sunlit clouds. Below them was a dark broad belt of forest sloping down to an ice-covered lake, in which some woody islands could be seen. At the beginning the western sky was clear, but gradually a dark bank of clouds rolled up, at last obscuring the mirage, but it reappeared several times when the sun broke through.

Mr. Penhallow, who has resided for some years in the service of the Japanese Government in Yezo, contributes to the last number of the *Canadian Record of Science* an article on the physical characteristics of the Ainos. Referring to the many contradictory reports as to the great hairiness of the Yezoines, his conclusion is that, although there are many exceptions, they generally possess a more than ordinarily hairy body, enough so at least to make them deserve the epithet of "hairy Kuriles." The bushy appearance of the hair and beard is doubtless due as much to the fact that the men never shave and seem rarely even to clip their beards, as to any natural excess of growth. The Aino of Saghalien offers a striking departure from the rule of hairiness which essentially characterises the Yezoine; and this would appear therefore not to be a race characteristic, but to be due to the peculiar and widely different conditions of life, dress, and exposure to which these people have been subjected. From

a considerable number of measurements, Mr. Penhallow summarises the physical characteristics of the Ainos as follows:—The forehead is usually high, though narrow; eyebrows heavy and overhanging; nose somewhat inclined to flatness, though but little more so than in Europeans; mouth wide, but well formed; chin well formed and medium size; eyes straight, brown, and dull; cheek-bones inclined to be prominent; facial angle high, the mean of the measurements giving an angle of 72°; the body is compact, well built, and muscular; much more than ordinarily hairy, skin of light colour, comparable to that of Europeans, and the average height is about 5 feet 2 inches.

THAT frogs have a formidable enemy in the common mouse is evidenced by the following incident. A correspondent, Mr. W. August Carter, of South Norwood, states that he observed, a short time since, several mice pursuing some frogs in a shed which was overrun with these reptiles. The alacrity of the latter, however, rendered the attacks of the mice futile for a considerable period. Again and again the frogs escaped from the clutches of their foes, but only to be recaptured, severely shaken, and bitten. The energy put forth by these reptiles was so great that they actually swayed their captors to and fro in their efforts to wrest themselves from their grasp. At length the wounds inflicted upon them rendered the frogs incapable of further resistance, and they were easily overpowered by the mice, which devoured a certain part of them.

IN a lecture recently delivered before the Scientific Society of Bamberg, Dr. Hartwig, the Director of the new Astronomical Observatory there sketched out the future work of that institution. It was well, he said, that an observatory should devote itself to some specialty, with which its name would be associated, as that of Paris was with the determination and mapping of the fixed stars, Greenwich with the movements of the moon, Vienna with comets, and so on. In a similar way Bamberg would occupy a certain limited field, and labour therein. In the first place it would undertake the systematic investigation of the parallaxes of the fixed stars, a work which had already been partially performed at the Cape Observatory for the southern, and at Newhaven in the United States for the northern hemisphere. Bamberg will be provided with a new 7-inch heliometer, the largest of its kind at present in the world, although the Cape Observatory will shortly be provided with one of the same size. The present Cape heliometer is a 4-inch, and that at Newhaven a 6-inch one. Dr. Hartwig said that this 7-inch heliometer is at present the finest instrument known to astronomy. He pointed out that at present the parallaxes of only eight or ten fixed stars were calculated, while about three thousand remain to be done, and this, he said, would take a single qualified observer more than thirty years to accomplish. He hoped that as Leipzig and Göttingen were about to be provided with heliometers, they would participate in the work, so that in a comparatively short time we may obtain a more accurate notion of the distance of many fixed stars and of their grouping in space. Another work which Bamberg would undertake is the investigation of the physical libration of the moon—a problem that has been studied at Königsberg since 1845, and in Strasburg since 1870. After describing at some length the instruments with which the new Observatory is provided, Dr. Hartwig concluded by assuring his hearers that with these an observatory would be established which would take a high place amongst existing astronomical institutions, and which would be excelled in Germany by the Observatories of Strasburg and Potsdam alone. The Bamberg Observatory, it should be stated, owes its existence to the munificence of a private individual, the late Dr. Remeis, a member of the Scientific Society of Bamberg.

THE *Darling Downs Gazette* of March 20 describes some recently discovered caves fifteen miles from Rockhampton, Queensland. A party, headed by Mr. W. M'Ilwraith, of the Rockhampton Natural History Society, recently visited the caves. From some wells on the route they saw the peaks of an uncommon range of hills. "They stand up in a fine sharp profile like the pinnacles and turrets of a stately Gothic pile. The vestibule of the wonderful structure is formed by an immense chasm in the rocks. Two walls of limestone or marble rock set in an acute angle rise on either side to a height of about 60 feet, and converge in front at a higher elevation. At 9 o'clock at night the party began exploring, and after clambering over a mass of detached, sharp-edged, pock-pitted rocks, got into a rocky chamber. Its walls were beautifully white in parts, and show the rock to be of limestone formation. They visited in succession caves of different dimensions, and named one the 'Chinese Joss-house.' It is a little recess off the passage: the walls are beautifully white, and stalactites and stalagmites unite to form beautiful pillars, the whole being wonderfully beautiful, reminding the visitors of Chinese ivory carved work. In the morning they continued their exploration, wandering through numerous passages, and crawling and slipping till they came to a large cavern. In one of the passages the bats extinguished their candles, and they returned to the upper regions. They then saw daylight streaming from the opposite side of the mountain, and estimated the distance from light to light at five chains or more. They returned to the starting-point, climbed a ladder, and traversed other passages, and crossed a gulf on a bridge formed of saplings. Eventually they reached a wide opening, and the light poured in from an opening in the caves. This latter is a large chamber, and in it are the roots of a tree, which have taken hold in the bottom of the cave, and hang like ropes. The most striking stalagmites in it resemble the head of an elephant and the bust of a man. Various caves were discovered, and also openings leading from one main suite of caves to another one. The cave particularly alluded to is called 'The Cathedral.' It is 50 feet long from the porch to the pulpit stairs, 30 feet across, and the ceiling is so lofty that the gleams of the candle did not reach it. There are stalactitic formations on the ceilings and floor, but the walls are plain, and have niches in some parts. Some of the party descended 60 feet here, and in another failed to reach the opening. The writer says, 'Wherever we went almost underground our footsteps had a hollow sound, and the conclusion we come to at present is that the region has been a hot-spring area, and the caves were formed by the action of hot water.'"

THE various species of Salmonidæ hatched out and reared by the Buckland Museum authorities have been turned into the Thames at Penton Hook, with a view of replenishing the stock of fish in that river. The Thames Angling Preservation Society are making arrangements to receive a consignment of land-locked salmon fry at their nursery again this year, in order to rear them for the Thames. The exertions now being made to re-stock the unpolluted portions of this river are sure to terminate in good results, indeed many of the trout taken lately are said to be the result of previous efforts made by pisciculturists in this direction.

ORNITHOLOGISTS, antiquarians, and librarians will in a few days have the opportunity of possessing a book which is said to be the only work published on the subject of duck decoys. It will be in quarto, with many illustrations, coloured and woodcut. Its author, Sir Ralph Payne-Gallwey, is already known to naturalists by his book on wild-fowl, issued some few years since by the publisher of the present volume, Mr. Van Voorst.

DR. VON HAAST writes that the large geological relief model of New Zealand, referred to in our recent article on the Colonial

and Indian Exhibition, has been prepared by Dr. James Hector, the Director of the Geological Survey of New Zealand, and forms part of the large exhibit of that gentleman. There are several large labels inside the glass case, in which the necessary explanations are given.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Mr. Angus Ogilvy ; two Black-tailed Parrakeets (*Polytelis melanura*) from South Australia, presented by Mr. James Thomson ; an Indian Cobra (*Naia tripudians*) from India, presented by Messrs. H. Thwaites and V. A. Julius ; a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain ; a Loggerhead Turtle (*Thalassochelys caouana*) from the Atlantic Ocean, presented by Mr. R. G. Fraser, R.N. ; a Rook (*Corvus frugilegus*), British, presented by Mr. H. J. Peckover ; a Black-faced Spider Monkey (*Ateles ater*) from Eastern Peru, a Crab-eating Raccoon (*Procyon cancrivorus*) from West Indies ; an Indian Cobra (*Naia tripudians*) from India, deposited ; two Spotted Hyænas (*Hyæna crocuta*) from South Africa, two Side-striped Jackals (*Canis lateralis*) from West Africa, a Griffon Vulture (*Gyps fulvus*), a Smooth Snake (*Coronella lævis*), a Viperine Snake (*Tropidonotus viperinus*), European, purchased ; two Triangular Spotted Pigeons (*Columba guinea*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

A CATALOGUE OF "COMPARISON" STARS.—Dr. N. M. Kam of Schiedam has published in *Verhandelingen der Koninklijke Akademie van Wetenschappen*, Deel. xxiv. (Amsterdam), a star catalogue compiled from the places of stars determined by meridian observations, which have been extracted from vols. i. to lxvi. of the *Astronomische Nachrichten*, and reduced to the epoch 1855·0. The positions of the stars contained in this catalogue were determined in connection with observations of planets and comets, and it was in compliance with Argelander's express desire that the work of collecting them and reducing the positions to a common epoch was commenced by Hoek, then Director of the Utrecht Observatory. Dr. Kam, who was Hoek's assistant, continued the work after the death of the latter, and has at length been able to publish his results. The principal catalogue contains the completely determined places of 4350 stars, and is followed by two subsidiary catalogues, the first giving the places of 236 stars, and the second those of 335 stars ; all of the latter, however, are incomplete, *i.e.* the place is given in one element only. The catalogues are followed by a comparison of the places of the stars contained in them with their places as given in the Bonn *Durchmusterung*, or, for stars south of − 2° Decl., with other authorities. Notes on proper motions, corrigenda, &c., are appended, which are of considerable interest and value. We hope that the work of collecting and cataloguing the class of stars here dealt with will be continued either by Dr. Kam or by some other astronomer as well fitted for the task as he has proved himself to be.

THE PARIS OBSERVATORY.—Admiral Mouchez, Director of the Paris Observatory, has recently published his annual report to the Council of the Observatory. It is a very instructive and interesting document, and affords gratifying evidence of the enterprise and energy with which the work of this great institution is carried on.

The most striking portion of the report is that which deals with the work of the Bros. Henry in astronomical photography, but as this, as well as M. Lœwy's ingenious device for determining the amount of astronomical refraction, have already been noticed in NATURE, it will not be necessary to again refer to them. Leaving these two great undertakings therefore on one side, the rest of the report exhibits a large amount of solid work. The meridian service has comprised 16,173 observations, 795 of the sun and planets. The instruments of the Salle Méridienne have been devoted to the observation of Lalande's stars. As the great Catalogue approaches completion, the stars still to be observed become more widely scattered, and fewer observations are necessarily secured. The division-errors of the Gambey circle are being carefully investigated by M. Périgaud, and the Garden circle has been used for the determination of the absolute positions of a number of circumpolar stars. A new flexure apparatus has been constructed by M. Gautier, and 603 stars have been already observed with it. The same ingenious artist has also devised a new mode of supporting a mercury trough, for freeing it from the effect of tremors, which has been found to work very satisfactorily. The equatorials have been employed as usual in observations of comets, minor planets, and nebulæ ; the equatorial of the east tower having been employed by MM. Henry in the revision of some of their photographic charts containing very faint stars, especially the Pleiades and the regions round Vega and ε Lyræ. In the department of the calculations, the calculations for the great Catalogue had been completed as far as 8h. of R.A., and were being carried on from 8h. to 12h. The Catalogue itself was printed up to No. 3800, and the manuscript prepared up to No. 4700. Of the volume of observations for 1882, seventy-three sheets had been printed, and the rest was in the printer's hands. The volume for 1883 had been commenced, and of the *Mémoires*, tome xviii., had been distributed, and tome xix. was in course of publication.

Several important investigations have also been carried on by individual members of the staff. M. Lœwy has devised a new method for determining the absolute co-ordinates of circumpolar stars, and M. Renan has published two notes on his experiments in application of these methods. M. Callandreau has published several notes on the theory of the figure of the planets and of the earth, and numerical tables for assisting in the calculation of ephemerides for minor planets ; whilst M. Prosper Henry has been engaged in devising suitable methods for the measurement and reduction of the photographic star-charts, which differ so widely from ordinary astronomical observations. A new determination of the length of the seconds pendulum has also been made by Capt. Defforges, of the Geographical Service, the length corrected to sea-level being found to be 0·99394m. Amongst the works to be carried out in the present year is the study of the movements of the soil by the aid of a multiplying seismograph devised by M. Bouquet de la Grye. The report concludes with a reproduction of a photograph of the Pleiades and a comparison of the results thus obtained by photography in a single hour with those obtained by M. Wolf in his study of the same group through the toil of years.

NOTES ON VARIABLE STARS.—Mr. Espin, the special observer to the Liverpool Astronomical Society, has recently commenced the issue of circulars calling attention to various variable stars or stars suspected of variation. Circular No. 1 gives an ephemeris for 10 Sagittæ, the next maximum, mag. 5·6, falling due June 5·4d., and the next minimum, mag. 6·4, June 11·1, period 8·317d. Circular No. 2 calls attention to the star D.M. + 8°, No. 3780, R.A. (1885·0) 18h. 32m. 51s., Decl. 8° 43′·5 N., as a probable variable. Circular No. 3 gives new elements for U Hydræ, R.A. 10h. 31·9m., Decl. 12° 40′·7 S., from whence it would appear that the next maximum is due 1886 June 25·5d. Circular No. 4 gives provisional elements for W. Cygni, R.A. (1886·0) 21h. 31m. 44s., Decl. 44° 51′·0 N., as follows :— P = 120 to 130 days, V = 5·8 ± to 7·5 ±, M = 1886 May 19 ±, m = 1886 Feb. 14 ±.

THE "CANALS" OF MARS.—M. Terby, in a note presented some little time ago to the Royal Academy of Belgium, drew attention to the occurrence in the drawings of Mars made by Herschel and Schrœter of several markings resembling the well-known Kaiser Sea in size and distinctness, and pointed out that M. Schiaparelli, in his observations of 1881–82, represented the "canal" Indus as developed to dimensions almost as great as those of the Kaiser Sea, and that this development coincided with the "gemination" or doubling of almost all the other canals. M. Faye now announces at the last meeting of the Académie des Sciences that M. Perrotin and the other observers at the Nice Observatory have recently been able to re-detect M. Schiaparelli's canals. The reality of the existence of the delicate markings discovered by the keen-sighted astronomer of Brera seems thus fully demonstrated, and it appears highly probable that they vary in shape and distinctness with the changes of the Martial seasons.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 JUNE 6–12

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 6

Sun rises, 3h. 47m.; souths, 11h. 58m. 23·3s.; sets, 20h. 9m.; decl. on meridian, 22° 41′ N.: Sidereal Time at Sunset, 13h. 10m.

Moon (at First Quarter on June 9) rises, 8h. 10m.; souths, 15h. 49m.; sets, 23h. 17m.; decl. on meridian, 15° 7′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	3 25	11 29	19 33	21 45 N.
Venus	2 10	9 7	16 4	10 20 N.
Mars	11 47	18 18	0 49*	5 28 N.
Jupiter	12 31	18 48	1 5*	2 43 N.
Saturn	5 26	13 37	21 48	22 43 N.

* Indicates that the setting is that of the following morning.

GEOGRAPHICAL NOTES

The French forces in Tonquin having now succeeded in occupying Lao-Kai, near the Chinese frontier, the capital of the Black Flag State, the whole course of the Red River in Tonquin is for the first time open to exploration. Accordingly two flat-bottomed gunboats with an exceedingly small draught have been built and equipped, and left Hanoi on April 3 to ascend the river, having on board officers whose duty it is to survey the river and the adjacent country, to fix the positions of the most important points, and to produce a map of the whole.

At the meeting of the Geographical Society of Paris on the 21st ult., M. de Lesseps referred to the works on the Panama Canal, and argued that locks or dams were unnecessary. M. Aubry gave a summary of a journey which he made in 1883 and 1884 to Choa and the Gallas country in pursuit of a mission with which he was charged by the Minister of Public Instruction. He collected a large number of mineralogical specimens, and studied the region from a geological and palæontological point of view. He also surveyed the courses of two rivers.

The Government of British North Borneo has secured the services of Capt. Beeston for the purpose of making a mineralogical and geographical survey of the country. He has started for the Segama River, which has already been visited by Frank Hatton, to investigate the localities in which gold is said to have been found.

At the instance of the Société de Géographie Commerciale of Nantes, a Commercial-Geographic Exhibition will be held in that city between June 15 and August 15 next. According to the programme the Exhibition will be divided into five classes: (1) scientific geography; (2) ethnography; (3) travelling and means of communication; (4) French and French-Colonial produce; (5) educational material.

ON RECENT PROGRESS IN THE COAL-TAR INDUSTRY[1]

Those who have read Goethe's episodes from his life, known as "Wahrheit und Dichtung," will remember his description of his visit in 1741 to the burning hill near Dutweiler, a village in the Palatinate. Here he met old Stauf, a coal philosopher, *philosophus per ignem*, whose peculiar appearance and more peculiar mode of life, Goethe remarks upon. He was engaged in an unsavoury process of collecting the oils, resin, and tar obtained in the destructive distillation of coal carried on in a rude form of coke oven. Nor were his labours crowned with pecuniary success, for he complained that he wished to turn the oil and resin to account, and save the soot, on which Goethe adds that, in attempting to do too much, the enterprise altogether failed. We can scarcely imagine, however, what Goethe's feelings would have been could he have foreseen the beautiful and useful products which the development of the science of a century and a half has been able to extract from Stauf's evil-smelling oils. With what wonder would he have regarded the synthetic power of modern chemistry, if he could have learnt that not only the brightest, the most varied colours of every tone and shade can be obtained from this coal-tar, but that some of the finest perfumes can, by the skill of the chemist, be extracted from it. Nay, that from these apparently useless oils, medicines which vie in potency with the rare vegeto-alkaloids can be obtained, and lastly, perhaps most remarkable of all, that the same raw material may be made to yield an innocuous principle, termed *saccharine*, possessed of far greater sweetness than sugar itself. The attainment of such results might well be regarded as savouring of the chimerical dreams of the alchemist, rather than expressions of sober truth, and the modern chemist may ask a riddle more paradoxical than that of Samson, "Out of the burning came forth coolness, and out of the strong came forth sweetness"; and by no one could the answer be given who had not ploughed with the heifer of science, "What smells stronger than tar, and what tastes sweeter than saccharine?" That these are matters of fact we may assure ourselves by the most convincing of all proofs—their money value, and we learn that the annual value of the products now extracted from an unsightly and apparently worthless material amounts to several millions sterling, whilst the industries based upon these results give employment to thousands of men.

Sources of the Coal-tar Products.—In order to obtain these products, whether colours, perfumes, antipyretic medicines, or sweet principle, a certain class of raw material is needed, for it is as impossible to get nutriment from a stone as to procure these products from wrong sources. All organic compounds can be traced back to certain hydrocarbons, which may be said to form the skeletons of the compounds, and these hydrocarbons are divisible into two great classes: (1) the paraffinoid, and (2) the benzenoid hydrocarbons. The chemical differences both in properties and constitution between these two series are well marked. One is the foundation of the fats, whilst the other class gives rise to the essences or aromatic bodies. Now all the colours, finer perfumes, and antipyretic medicines referred to, are members of the latter of these two classes. Hence if we wish to construct these complicated structures, we must employ building materials which are capable of being cemented into a coherent edifice, and therefore we must start with hydrocarbons belonging to the benzenoid series, as any attempt to build up the colours directly from paraffin compounds would prove impracticable. Of all the sources of hydrocarbons, by far the largest is the natural petroleum oils. But these consist almost entirely of paraffins, and hence this source is commercially inapplicable for the production of colours. We have, however, in coal itself, a raw material which

[1] A Discourse by Prof. Sir Henry E. Roscoe, M.P., LL.D., F.R.S., delivered at the Royal Institution, Friday, April 16, 1886.

by suitable treatment may be made to yield oils of a valuable character. Of these treatments, that followed out in the process of gas-making is the most important, for in addition to illuminating gas in abundant supply, tar is produced which contains principally that benzenoid class of substances already referred to, and which, to use the words of Hofmann, "is one of the most wonderful productions in the whole range of chemistry." The production of these latter as distinguished from the paraffinoid group appears to depend upon a high temperature being employed to effect the necessary decomposition.

The quantity of coal made into coke for use in the blast furnace is larger than that distilled for gas-making, no less than between eleven and twelve million tons of coal being annually consumed in the blast furnaces of this country in the form of coke, and capable of yielding two million tons of volatile products. Up to recent times, however, the whole of these volatile products has been burnt and lost in the coke ovens. But lately, various processes have been devised for preventing this loss, and for obtaining the oils, which might be made available as colour-producing materials. It is, moreover, a somewhat remarkable fact that only in one or two cases have the conditions been complied with which render it possible to obtain the necessary benzenoid substances. In the ordinary coking ovens, as well as in the blast furnaces, although the temperature ultimately reached is far in excess of that needed to form the colour-giving hydrocarbons, yet the heating process is carried on so gradually that the volatile products from the coal are obtained in the form of paraffinoid bodies mainly, and hence are useless for colour-making purposes. Amongst the few coking processes in which the heat is suddenly applied, and consequently a yield of colour-giving

hydrocarbons is obtained, may be mentioned the patented process of Simon-Carvès, the use of which is now spreading in England and abroad. The tar obtained in this process is almost identical in composition with the average gas-works tar, whilst the coke also appears to be equal for iron-smelting purposes to that derived from other coke ovens. A third source of these oils yet remains to be mentioned, viz. those obtained as a by-product in blast furnaces fed with coal.

Another condition has, in addition, to be considered in this industry, and that is the nature of the coal employed for distillation. It is a well-known fact that if Lancashire cannel be exclusively employed in gas-making a highly-luminous gas is obtained, but the tar is too rich in paraffins to be a source of profit to the tar-distiller, whilst, on the other hand, coal of a more anthracitic character, like that from Newcastle or Staffordshire, yields a tar too rich in one constituent, viz. naphthalene, and too poor in another, viz. benzene. It is also known to those engaged in carbonising coal principally for the sake of the tar that the coal from different measures, even in the same pit, yields tars of very different constitution. That under these varying conditions products of varying composition are obtained is a result that will surprise no one who considers the complicated chemical changes brought about in the process of the destructive distillation of coal.

History of Benzene and its Derivatives.—Having thus sketched the principles upon which the formation of these valuable tar colours depends, we should do wrong to pass over the history of the discovery of benzene (C_6H_6), which contributed so much to the unlocking of the coal-tar treasury.

Faraday in 1825 discovered two new hydrocarbons in the oils

obtained from portable gas. One of these was found to be butylene (C_4H_8); to the other Faraday gave the name of bicarburet of hydrogen, as he ascertained its empirical formula to be C_2H ($C = 6$). By exploding its vapour with oxygen, he observed that one volume contains 36 parts by weight of carbon to 3 parts by weight of hydrogen, and its specific gravity compared with hydrogen is therefore 39.[1]

Mitscherlich, in 1834, obtained the same hydrocarbon by distillation of benzoic acid, $C_7H_6O_2$, with slaked lime, and termed it benzin. He assumed that it is formed from benzoic acid simply by removal of carbon dioxide. Liebig denied this, adding the following editorial note to Mitscherlich's memoir:—"We have changed the name of the body obtained by Prof. Mitscherlich by the dry distillation of benzoic acid and lime, and termed by him benzin, into benzol, because the termination 'in' appears to denote an analogy between strychnine, quinine, &c., bodies to which it does not bear the slightest resemblance, whilst the ending in 'ol' corresponds better to its properties and mode of production. It would have been perhaps better if the name which the discover, Faraday, had given to this body had been retained, as its relation to benzoic acid and benzoyl compounds is not any closer than it is to that of the tar or coal from which it is obtained."

Almost at the same time Péligot found that the same hydrocarbon occurs, together with benzone, $C_{13}H_{10}O$ (diphenylketone, $CO(C_6H_5)_2$), in the products of the dry distillation of calcium benzoate.

The different results obtained by Mitscherlich and Péligot are represented by the following formulæ:—

$$C_7H_6O_2 + CaO = C_6H_6 + CaCO_3.$$
$$(C_7H_5O_2)_2Ca = C_{13}H_{10}O + CaCO_3.$$

Péligot obtained benzene only as a by-product, exactly as in the preparation of acetone (dimethylketone) from calcium acetate a certain quantity of marsh gas is always formed.

It is not clear how Liebig became acquainted with the fact that benzene is formed by the dry distillation of coal, as his pupil Hofmann, who obtained it in 1845 from coal-tar, observes: "It is frequently stated in memoirs and text-books that coal-tar oil contains benzene. I am, however, unacquainted with any research in which this question has been investigated." It is, however, worthy of remark that about the year 1834, at the time when Mitscherlich had converted benzene into nitrobenzene, the distillation of coal-tar was carried out on a large scale in the neighbourhood of Manchester; the naphtha which was obtained was employed for the purpose of dissolving the residual pitch, and thus obtaining black varnish. Attempts were made to supplant the naphtha obtained from wood-tar, which at that time was much used in the hat factories at Gorton, near Manchester, for the preparation of "lacquer," by coal-tar naphtha. The substitute, however, did not answer, as the impure naphtha left, on evaporation, so unpleasant a smell, that the workmen refused to employ it. It was also known, about the year 1838, that wood-naphtha contained oxygen, whilst that from coal-tar did not, and hence Mr. John Dale attempted to convert the latter into the former, or into some similar substance. By the action of sulphuric acid and potassium nitrate, he obtained a liquid possessing a smell resembling that of bitter almond oil, the properties of which he did not further investigate. This was, however, done in 1842 by Mr. John Leigh, who exhibited considerable quantities of benzene, nitrobenzene, and dinitrobenzene, to the Chemical Section of the British Association meeting that year in Manchester. His communication is, however, so printed in the Report, that it is not possible from the description to identify the bodies in question.

Large quantities of benzene were prepared in 1848, under Hofmann's direction, by Mansfield, who proved that the naphtha

[1] *Phil. Trans.*, 1825, p. 440.

in coal-tar contains homologues of benzenes, which may be separated from it by fractional distillation. On the 17th of February, 1856, Mansfield was occupied with the distillation of this hydrocarbon, which he foresaw would find further applications, for the Paris Exhibition, in a still. The liquid in the retort boiled over and took fire, burning Mansfield so severely that he died in a few days.

The next step in the production of colours from benzene and toluene is the manufacture of nitrobenzene, $C_6H_5NO_2$, and nitrotoluene, $C_7H_7NO_2$. The former compound, discovered in 1834 by Mitscherlich, was first introduced as a technical product by Collas under the name of artificial oil of bitter almonds, and Mansfield in 1847 patented a process for its manufacture. It is now used for perfuming soap, but mainly for the manufacture of aniline ($C_6H_5NH_2$) for aniline blue and aniline black and for magenta. It is made on a very large scale by allowing a mixture of well-cooled fuming nitric acid and strong sulphuric acid to run into benzene contained in cast-iron vessels provided with stirrers.

To prepare aniline from nitrobenzene, this compound is acted upon with a mixture of iron turnings and hydrochloric acid in a cast-iron vessel. Commercial aniline is a mixture of this compound with toluidine obtained from toluene contained in commercial benzene. Some idea of the magnitude of this industry may be gained from the fact that in one aniline works near Manchester no less than 500 tons of this material are manufactured annually. From the year 1857, after Perkin's celebrated discovery[1] of the aniline colours, up to the present day, the history of the chemistry of the tar products has been that of a continued series of victories, each one more remarkable than the last.

Coal-tar Colours.—To even enumerate the different chemical compounds which have been prepared during the last thirty years from coal-tar would be a serious task, whilst to explain their constitution and to exhibit the endless variety of their coloured derivatives which are now manufactured would occupy far more time than is placed at my disposal. On the industrial importance of these discoveries the speaker reminded his audience of the wonderful potency of chemical research, as shown by the fact that the greasy material which in 1869 was burnt in the furnaces or sold as a cheap waggon grease at the rate of a few shillings a ton, received two years afterwards, when pressed into cakes, a price of no less than one shilling per pound, and this revolution was caused by Gräbe and Liebermann's synthesis of alizarin, the colouring matter of madder,[2] which is now manufactured from anthracene at a rate of more than two millions sterling per annum; and it is stated that an offer was once made, in the earlier stages of its history, by a manufacturer of anthracene to the Paris authorities to take up the asphalt used in the streets for the purpose of distilling it, in order to recover the crude anthracene.

Again, we have in the azo-scarlets derived from naphthalene a second remarkable instance of the replacement of a natural colouring matter, that of the cochineal insect, by artificial tar-products, and the naphthol-yellows are gradually driving out the dyes obtained from wood extracts and berries. It is, however, true that some of the natural dye-stuffs appear to withstand the action of light better than their artificial substitutes, and our soldiers' red coats are still dyed with cochineal.

The introduction of these artificial scarlets has, it is interesting to note, greatly diminished the cultivation of cochineal in the Canaries, where, in its place, tobacco and sugar are now being largely grown.

Let us next turn to inquire as to the quantities of these various products obtainable by the distillation of one ton of coal in a gas-retort. The six most important materials found in gas-tar from which colours can be prepared are:—

1. Benzene.	4. Metaxylene (from solvent naphtha).
2. Toluene.	5. Naphthalene.
3. Phenol.	6. Anthracene.

The average quantity of each of these six raw materials obtainable by the destructive distillation of one ton of Lancashire coal is seen in Table I. Moreover, this table shows the average amount of certain colours which each of these raw materials yields, viz.:—

1. } 2. } Magenta 0·623 lb.	4. (*Xylidine* 0·07 lb.) 5. Vermilline scarlet 7·11 lbs.
3. Aurin 1·2 lb.	6. Alizarin 2·25 lbs. (20 per cent.)

Further, it shows the dyeing power of the above quantities of each of these colours, all obtained from one ton of coal, viz.:—

1 and 2. Magenta, 500 yards of flannel.
3. Aurin, 120 yards of flannel 27 in. wide.
4 and 5. Vermilline scarlet, 2560 yards of flannel.
6. Alizarin, 255 yards Turkey red cloth.

Lastly, to point out still more clearly these relationships, the dyeing power of one pound of coal is seen in the lowest horizontal column, and here we have a party-coloured flag, which exhibits the exact amount of colour obtainable from one pound of Lancashire coal.

Let us moreover remember, in this context, that no less than ten million tons of coal are used for gas-making every year in this country, and then let us form a notion of the vast colouring power which this quantity of coal represents.

The several colours here chosen as examples are only a few amongst a very numerous list of varied colour derivatives of each group. Thus we are at present acquainted with about sixteen distinct yellow colours; about twelve orange; more than thirty red colours; about fifteen blues, seven greens, and nine violets; also a number of browns and blacks, not to speak of mixtures of these several chemical compounds, giving rise to an almost infinite number of shades and tones of colour. These colours are capable of a rough arrangement according as they are originally derived from one or other of the hydrocarbons contained in the coal-tar. The fifty specimens of different colours exhibited may thus be classified, but in Table II., for the sake of brevity, only the commercial names and not the chemical formulæ of these compounds is given.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Prof. Liveing has been appointed Chairman of the Examiners for the Natural Sciences Tripos, and Mr. James Ward of those for the Moral Sciences Tripos. There were 106 candidates for the first part of the Natural Sciences Tripos recently held.

Attention has recently been given to the preservation of University buildings from fire, and serious defects have been, or are being, remedied. Such matters should be carefully thought out in regard to every museum and library, and it is to be hoped that attention will be constantly given to the efficiency of means of prevention and extinction of fires. The report on this subject in No. 636 of the *Cambridge University Reporter* is well worthy of the study of officials concerned in guarding precious scientific collections.

Prof. Darwin will lecture in the Long Vacation on the Theory of the Potential, Attractions, and the Figure of the Earth, the first lecture being on Tuesday, July 13.

A recent discussion of a report by the Special Board on Medicine emphasised the desirability of teaching elementary physics as part of general education to those intending to become medical students, and showed that the new "extra subjects" of the Previous Examination do not satisfactorily secure this, dynamics and a mathematical treatment being required, rather than experimental acquaintance with the physical forces. Mr. Oscar Browning said the interests of education were suffering terribly from the want of agreement as to what schoolboys ought to be taught. Mr. Shaw remarked on the importance of a training in inductive reasoning for medical students, for their whole practice would consist in drawing inductions.

The grants from the Worts Fund to Messrs. Bateson, Seward, Gadow, and Potter, to which we recently referred, have been voted by the Senate.

Prof. Alfred Marshall is giving a prize of 15*l.* annually for Political Economy, to be open to all members of the University under the M.A. degree. The examination is to consist of the papers on Political Economy in Part I., and on Advanced Poli-

ical Economy in Part II. of the Moral Sciences Tripos. The first award is to be in June 1887. He desires to concentrate the attention of some students more systematically than hitherto, noting that on some sides Natural Science studies constitute the best preparation.

During the last ten years, grants from the Worts Fund for Antiquarian and Literary subjects have amounted to 1100*l*.; for Biological and Geological subjects, to 1225*l*.; and for Medical subjects, to 100*l*.

Sir J. Lubbock's Rede Lecture will be delivered on Wednesday, June 9, at 2 p.m., in the Senate House, subject, "On the Forms of Seedlings and the Causes to which they are due."

SOCIETIES AND ACADEMIES

London

Royal Society, May 27.—"The Influence of Stress and Strain on the Physical Properties of Matter. Part I. Elasticity (continued). The Effect of Magnetisation on the Elasticity and the Internal Friction of Metals." By Herbert Tomlinson, B.A. Communicated by Prof. W. Grylls Adams, M.A., F.R.S.

The principal object of this investigation was to test the soundness of the view advanced by Prof. G. Wiedemann respecting the cause of the internal friction of a torsionally oscillating wire. According to this view, the internal friction is mainly due to permanent rotation to-and-fro of the molecules about their axes; it seemed probable, therefore, that experiments on the effects of magnetising a wire, either longitudinally with a helix, or circularly by passing a current through it, would aid in elucidating the matter.

The following are the principal results which have been obtained:—

(1) When the deformations produced by the oscillations are small, the internal friction of a torsionally vibrating wire of iron or steel is not affected by sustained longitudinal magnetisation of moderate amount. The internal friction is also not affected by the sustained magnetisation even when the latter is carried to the point of saturation, provided the magnetising current be, previously to experimenting, reversed a great number of times. When no previous reversals have been made, the internal friction is slightly increased by intense magnetisation.

(2) When the deformations produced by the oscillations are large, the internal friction is very sensibly increased by sustained longitudinal magnetisation of large amount.

(3) The torsional elasticity is entirely independent of any sustained longitudinally magnetising stress which may be acting upon an iron or steel wire, provided the deformations produced by the torsional oscillations be small. When the deformations are large, the number of oscillations executed in a given time is very slightly lessened by sustained longitudinal magnetisation of large amount.

(4) When the magnetising current is interrupted and, to a greater extent, when it is reversed repeatedly whilst the wire is oscillating, the internal friction is increased, provided the magnetising stress be of moderate amount. The increase of internal friction may become very considerable when the magnetising stress is great.

When the number of interruptions or reversals in a given time of the magnetising current exceeds a certain limit, the effect on the internal friction begins to decline.

(5) When the deformations produced by the oscillations are small, the torsional elasticity is not affected by either repeatedly interrupted or reversed longitudinal magnetisation even when the magnetising stress is large.

(6) There exists a limit of magnetic stress within which no permanent rotation whatever of the molecules is produced. This limit may be widened by previous repeated reversals of a large magnetising stress.

(7) The passage of a moderate electric current, whether sustained or interrupted, through a torsionally vibrating wire of iron, steel, or nickel does not affect, except by heating, either the internal friction or the torsional elasticity, provided the deformations produced by the oscillations be small.

(8) The effect of longitudinal magnetisation, even when carried to the point of saturation, on the longitudinal oscillation of an iron or steel wire, is *nil*.

(9) The passage of an electric current, whether sustained or interrupted, through a longitudinally oscillating wire of iron or steel does not, except by heating, affect the number of oscillations executed in a given time.

Chemical Society, May 6.—Dr. Hugo Muller, F.R.S., President, in the chair.—Messrs. John W. King, William Herbert Hyatt, and George T. Holloway were admitted Fellows of the Society.—The following papers were read:—Paranitrobenzoylacetic acid and some of its derivatives, by Dr. W. H. Perkin, jun., and Dr. E. Bellinot.—An acetic ferment which forms cellulose, by Adrian J. Brown.

Victoria Institute, May 28.—Annual Meeting.—The chair being taken by Prof. Stokes, P.R.S., Capt. Francis Petrie, as Honorary Secretary, read the report, which showed that the home, colonial, and American members were now upwards of 1150, and an increasing number of leading men of science had contributed to its transactions, and the Institute was much indebted to many other scientific men of eminence, at present outside its ranks, who had kindly given their aid and advice, so that the Institute might the more worthily foster a true appreciation of the results of scientific inquiry.—Prof. Hull, F.R.S., Director of the Geological Survey of Ireland, delivered the address, in which he gave an account of the work, discoveries, and general results of the recent Geological and Geographical Expedition to Arabia and Western Palestine, of which he had charge. Prof. Hull, having sketched the course taken by the scientific Expedition (which to a considerable extent took the route ascribed to the Israelites), the physical features of the country, evidences of raised beaches, &c., showed that at one time an arm of the Mediterranean had occupied the valley of the Nile as far as the First Cataract, the level of the land being 200 feet lower than at present (an opinion which had also been arrived at by another of the Institute's members, Sir W. Dawson), and that, at the time of the Exodus, the Red Sea ran up into the Bitter Lakes, and clearly must have formed a barrier to the travellers' progress at that time; he then alluded to the great changes of elevation in the land eastward of these lakes, mentioning that the waters of the Jordan valley once stood 1300 feet above their present height. The various geological and geographical features of the country were so described as to make the address a condensed report of all that is now known of that part of the East.—A vote of thanks was accorded to Dr. Hull, after which the members and their guests adjourned to the museum, where refreshments were served.

Edinburgh

Mathematical Society, May 14.—Dr. R. M. Ferguson, President, in the chair.—Mr. J. S. Mackay gave a construction, due to the Right Hon. H. C. E. Childers, for solving the problem of medial section; Mr. W. Peddie read the second part of a paper on the theory of contour lines and its application to physical science; and Mr. A. Y. Fraser submitted a paper, by Mr. Charles Chree, on the vibrations of a spherical or cylindrical body surrounded by or containing fluid.

Paris

Academy of Sciences, May 24.—M. Jurien de la Gravière, President, in the chair.—Order of appearance of the first vessels in the leaves of the Cruciferæ: mixed formation (part 5), by M. A. Trécul. In a previous paper the author showed that the primary lobes in the type of mixed formation presented by certain Cruciferæ appear on either side of the young leaves in two superimposed series—a lower *basipetal* and an upper *basifugal*. He now proves that the first vessels of the nervous system corresponding to these lobes usually appear in the same order. Those opposed to the lobes of the basifugal series follow from below upwards, while those opposed to the lobes of the basipetal series make their appearance successively from above downwards.—A study of the movements communicated to the air by the action of a bird's wing: M. Müller's experiments, by M. Marey. A description is given of M. Müller's mechanical experiments, which are conducted at night by the aid of phosphorescent vapours, and during the day by means of smoke in the way adopted by Tyndall.—Note accompanying the presentation of M. Verbeek's fresh studies on the Krakatão eruption, by M. Daubrée. Besides a detailed account of the eruption this comprehensive work contains a full description of the meteorological and magnetic phenomena attending it, together with some theoretical considerations on their causes. The author calculates that the quantity of matter ejected was at least 18 cubic kilometres in volume, all incoherent, consequently unaccompanied by any flow of lava.—Presentation of various maps of France, Algeria, Tunisia, and Africa, issued by the Geo-

graphical Service of the Army, by M. Perrier. Amongst these maps are one of France, scale 1 : 200,000, comprising the districts of Amiens, Melun, Lille, Mézières; one of Algeria, part 6, scale 1 : 50,000, districts of Azeffun, Jebel-Filfila, Jemmapes, Ben-Harun, Aine-Bessem, Rio Salado; and one of Tunisia, scale 1 : 200,000, districts of Nefta, Rejem-Matong, Dwirat, Wed-Fessi.—Note on a new form of purulent infection following an acute attack of pneumonia, by M. Jaccoud.—Researches on the organisation of the star-fish, by M. Edm. Perrier. Amongst the collections brought back by the Cape Horn Mission were several specimens of a new species of star-fish (*Asterias hyade i*, E. P.), with their young still attached, a circumstance which has helped to throw fresh light on some disputed points connected with the anatomical structure of these animals.—Observations of the new comets 1886 *a* (Brooks I.) and 1886 *b* (Brooks II.) made at the Observatory of Nice (Gautier equatorial), by M. Charlois.—On the geography of the Central Tunisian seaboard, by M. Rouire. A careful survey of the section of the coast between Hammamet and Susa has determined the existence of a large marine inlet at the head of Hammamet Bay, which receives all the drainage of Central Tunisia. It was also ascertained that at some more or less remote period the Halk-el-Mengel Sebkha was certainly navigable.—Determination of the absolute value of the wavelength of the ray D_2, by M. J. Macé de Lépinay. A fresh attempt to settle this disputed point gives the general result—

$$5 \cdot 8917 \times 10^{-5} \text{ (millilitre)}^{\frac{1}{3}};$$

and in the air, at 0°, normal pressure—

$$5 \cdot 8900 \times 10^{-5} \text{ (millilitre)}^{\frac{1}{3}}.$$

—On a visual illusion: apparent motion of a small object when slightly illumined amid the surrounding darkness, by M. Aug. Charpentier.—A new electric fuse for exploding mines charged with powder or dynamite, by MM. Scola and Ruggieri. For this fuse the authors claim that it prevents all accidents from slow combustion, and also removes some other dangers and difficulties attending mining operations.—Note on an apparatus intended to test the efficacy, or ascertain defects in the preparation, of electric fuses, by M. Ducretet.—Description of the cyclone that swept over Madrid on May 12, by M. A. F. Noguès.—On two different conditions of the black oxide of copper, by M. Joannis.—Action of the air, silica, and kaolin on the alkaline haloid salts: new methods of preparing hydrochloric acid, chlorine, and iodine, by M. Alex. Gorgeu.—On the oxidation of oils, by M. Ach. Livache.—On a little-known cause of corrosion in steam-boilers, by MM. D. Klein and A. Berg.—On a new means of employing the iodo-iodurctted reaction in the research of the alkaloids, and especially of the leucomaïnes in urine, by MM. Chibret and Izarn.—A fresh study of Entoniscus (*E. kossmanni*, *E. fraissi*, *E. moniezii*), by MM. A. Giard and J. Bonnier.—On the embryogeny of Comatula (*C. mediterranea*), by M. J. Barrois.—Observations regarding the nervous system and certain organic features of the scutibranch gasteropods, by M. E. L. Bouvier.—On a new Ichthyobdella, by M. R. Saint Loup. This species, which the author describes under the name of *Scorpænobdella elegans*, was recently observed in the Marine Zoological Laboratory at Marseilles.—On the superficial vascular apparatus of fishes, by M. P. de Sède.—On a fungus developed in the human saliva, by M. Galippe. This fungus, discovered in some saliva filtered by Pasteur's apparatus, and cultivated in Van Tieghem's cellules, belongs to the family of the Monilia. The author proposes to name it *Monilia sputicola* (sp.n.).—Remarks on the fifth volume of M. Habich's *Anales de Construcciones civiles y de Minas*, presented to the Academy, by M. Daubrée. To this volume M. Chalon contributes a paper on the prehistoric monuments of Peru, which show a remarkable resemblance to the menhirs, cromlechs, dolmens, and other "Druidical" remains in the west of Europe. They occur in large numbers in every part of the country.—At the request of M. de Lesseps, the President appointed a Commission comprising the members of the Sections for Geography, Navigation, and Astronomy, with MM. Daubrée, Favé, Lalanne, and de Jonquières to study the differences of level caused by the tides in the Pacific and Atlantic Oceans.

STOCKHOLM

Academy of Sciences, April 14.—On the results of some experiments on the condition of electricity in a vacuum, by Prof. E. Edlund.—On the power and fineness of the hollow muscles of the frog, by Herr C. G. Santesson.—On the oxidation of cymal, and on nitrocymal, by Prof. O. Widman and Dr. J. O. Bladin.—Mineralogical notes, by Dr. G. Flink.—Some remarks on the geological map of Sweden, by Herr E. Törnebohm.—Determination of the definite elements of the orbit of the Comet VIII. (1881), by Dr. K. G. Olsson.—Micrometrical determinations of some telescopic star clusters, by Prof. H. Schultz.—Contributions to the theory of wave-motions in a gaseous medium, by Prof. A. V. Backlund.—On the integration of the differential equation in the problem of N bodies, by Prof. G. Dillner.

May 12.—On a new method for determining the velocity of the electric molecules in a current of a certain power, by Prof. Edlund.—Contributions to the knowledge of the discharge of the Ruhmkorff coil, by Hr. T. Moll.—A method for increasing the convergence of periodical series, by Hr. C. Charlier.—Research on a non-linear differential equation of the second order, by Prof. H. Gyldén.—An account of the Zoological Station of Christineberg, in the province of Bohus, belonging to the Academy, by Prof. Sven Lovén.—Researches on the changes of the arsenious oxide in contact with putrid animal matters, by Prof. Hamberg.—A balance constructed by Hr. F. J. Lemcke for determining the consumption of the normal light in the measurement of the power of the light, exhibited by Prof. F. L. Ekman.—New or imperfectly known Isopoda, part 3, by Dr. C. Bavallius.—On naphtoë acids, by Dr. Ekstrand.

THE 43-TON GUN EXPLOSION

THE bursting of the 43-ton gun on board the *Collingwood* has naturally attracted considerable attention from men of science as well as from the general public, and it may not be out of place at the present time to compare the ideas of scientific men with the data given in text-books published by authority and put into the hands of artillery officers for purposes of instruction.

The latest gunnery text-book is that compiled by Major Mackinlay, R.A., and published in 1883. In it is a table compiled by another artillery officer, in which is given the calculated and actual results obtained from all classes of ordnance, among them being the 12″ B.L. gun of 43 tons, Mark II., the gun which burst on board the *Collingwood.*

The powder charge is given as 286 lbs. prismatic, projectile 720 lbs.; the total work theoretically producible from the expansion of the charge in the bore 22,884 foot tons; the actual work produced in muzzle energy of projectile 17,180 foot tons. There is therefore, according to the table, a loss of 5704 foot tons to be expended—externally in expelling the powder gases, displacing the atmosphere, and recoil; internally in heating and stretching the gun, in friction of the gas check and gases, and rotating the shot.

In a lecture delivered in January 1885, just after the bursting of the *Active's* 6″ gun, Mr. Wm. Anderson pointed out that the lost work was very much greater than was usually imagined, and he went through a calculation on thermo-dynamical principles of the forces produced in a 10″ B.L. gun. Taking Mr. Anderson's formulæ and adapting them to the 12″ B.L. gun, we shall not have to proceed far before finding out how erroneous is the table given in the text-book. We will only examine the forces external to the gun (*i.e.* those producing recoil), as Mr. Anderson's accuracy on these points has been indorsed by Col. Moncrieff, C.B., F.R.S., and we shall neglect internal forces employed in friction stretching and heating the gun—forces difficult to estimate, and on which there is some difference of opinion.

As to the energy of the projectile there can be no question, but taking the terminal pressure at 3 tons (we believe it has risen as high as 5·5 to 6 tons) the energy of the expelled gases is 12,208 foot tons, that expended in lifting the atmosphere 2501 tons, together 14,714 foot tons; so that, neglecting internal forces altogether—and these are no small quantity—we have 14,714 foot tons of energy against 5704 in the text-book.

We can only conclude that the pressure corresponding to this difference, as well as that due to the forces expended inside the bore, have been entirely neglected by the designers of the guns.

The powder with which the gun was burst was that known as "cocoa"; this powder, while diminishing the maximum pressure carries it further down the bore (a most dangerous thing for guns weak in the chase), and increases the mean and final pressures, and the muzzle velocity; therefore the calculation we have given is probably within the mark for an equal weight of cocoa powder.

The reason for the errors we have pointed out may probably be found in the blind confidence placed in the indications of crusher gauges. It is well known that a certain length of time must be taken up in the compression of all metals, and it is extremely doubtful whether something near the two-hundredth part of a second in which the explosion takes place is sufficient for the compression of copper cylinders, especially when comparisons are made between those near the breech, which are longer under the influence of the powder gases, and those in the muzzle, which are not acted on for any appreciable time.

The only item in the above estimates which has been ascertained by experiment is the muzzle velocity, the others are the result of calculation, and although Col. Moncrieff tells us they are to be trusted when measured in recoil, it would be far more satisfactory were they ascertained by direct experiment.

Means for verification have been pointed out, and although we believe the Government is provided with the instruments nothing has yet been done with them.

The failure of the *Collingwood's* gun raised hopes in the minds of many that at last a proper inquiry into the question would be held; but it has been referred back to the same Committee, associated with the same civilians (except Mr. Leece, who is dead), who recommended that the gun "should remain unaltered," but that "the charge of 295 lbs. of cocoa powder should not be exceeded."

They therefore are to sit in judgment on themselves, and if they relied on the same data when recommending certain additional strength should be given to other guns, as they did when merely limiting the charge of the 12″, what reason is there for supposing that the results with other guns will differ from this one except in loss of life and damage done?

GEOLOGY OF TURKESTAN

Turkestan; a Geological and Orographical Description based upon Data collected during the Journeys of 1874 *to* 1880. By J. V. Moushketoff. Pp. 714. With Map and Engravings. Russian. (St. Petersburg, 1886.)

FOR several years past all who take an interest in Central Asia have followed with great interest the yearly reports published by Profs. Romanovsky and Moushketoff on their geological explorations in the mountains of the Tian-Shan, the high plateaux of the Pamir, and the lowlands of the Amu-daria. The extensive character of these explorations, prosecuted for several consecutive years, and the practical experience of the two Russian geologists promised that new light would soon be thrown on several important but doubtful points in the geology of this most interesting region; but the appearance of their works has been delayed for some years. We have, however, now before us the first volume of M. Moushketoff's work, and when the whole, which will comprise three large volumes, as also M. Romanovsky's work on the same subject, is published, we shall have an almost complete picture of the geology of this region which contains the key to so many important geological questions in Europe.

The first volume of M. Moushketoff's "Turkestan" consists of two parts. The first is an analysis of all explorations made in Turkestan up to 1884; and, the literature of the subject being scattered in periodicals, it will be of great value for the geographer. All the Russian and English explorations are mentioned, and the chief of them briefly analysed. The second part contains a description of the journeys of the author in the "Turan or Aral basin," including Samarkand, the western outskirts of the Tian-Shan, the valley of Ferganah, the western outskirts of the Pamir and Alay region, the valley of the Amu-daria from Termez to Khiva, and the Kyzyl-kum sands. A summary concludes the volume, which is accompanied by a novelty that will agreeably surprise geologists, namely, a geological map of Russian Turkestan, on a scale of 67 miles to an inch. Another map, on a scale of 20 miles to an inch, is in course of preparation, that now published being only intended to show the extension and limits of four great geological subdivisions: the Post-Tertiary deposits; the Tertiary, together with the Chalk, Jurassic, and Trias; the Primary, including the Archæan crystalline slates; and the unstratified crystalline rocks (granites, porphyries, diabases, and so on). Of course, it is regrettable that the Secondary deposits could not be separated from the Tertiary; but we must wait for the appearance of the promised map on a larger scale.

As to the conclusions arrived at in this volume, we may remark at once that the personal inclinations of the author being chiefly directed to petrography on the one hand, and dynamic geology on the other, these two departments have received most attention; while Prof. Romanovsky, being a well-known palæontologist, has devoted his chief attention and wide practical knowledge to the discrimination of the different subdivisions of the sedimentary deposits explored by him. M. Romanovsky having published almost every year very valuable reports on his summer's work, his researches are embodied in M. Moushketoff's work, so that each is complementary to the other.

Nearly the whole of the Aral basin (and we have seen that the author includes under this name the wide tracts east and south-east of Lake Aral) is covered by Chalk, Tertiary, and Post-Tertiary deposits; the remaining portion, that is, no more than one-twentieth of the area, being occupied by crystalline unstratified rocks, metamorphosed slate, and Palæozoic deposits which appear from below the above. A mere glance at a topographical map of the region would be sufficient to indicate their extent—all the hills rising amidst the wide steppes being built up of Palæozoic or Archæan rocks. The Devonian limestones of the mountains Urda-bashi and Karatash; the syenites, diabases, and crystalline slates of the Mogol-tau, Kochkar-ata, and Karnak mountains; and the Devonian and Carboniferous limestones of the Kazy-kurt hills are in this category. Some gold, silver-and-lead ores, copper, as also almandine and beryl, are found in these mountains. It is interesting also to notice that the crystalline rocks in the Palæozoic islands scattered amidst the steppes are much more metamorphosed than the corresponding rocks in the Tian-Shan mountains. They have obviously been long subject to the influence of water, which once covered what is now the steppe region.

Jurassic deposits are the next geological formation found in the East Aral basin. The lowest strata seem, however, to belong to the Rhætic subdivision—the few remains of plants which they contain being some of them Jurassic, while others should be recognised as Rhætic, and the third Triassic. They contain no traces of marine origin, and only one fresh-water shell, the *Anadonta boroldaica*, Romanovsky. It must therefore be concluded that throughout the Triassic and Jurassic periods nearly all Turkestan was a land having on its borders numerous lakes containing sweet or brackish water. These Jurassic deposits appear only on the borders of the East Aral basin: namely, on the Baidam and Saram rivers, and in Ferganah; in the west they are known on the Mangishlak peninsula (Caspian). Everywhere they contain most valuable deposits of coal. We may add that the geologist will thus find, in the Aral basin, the well-known geological feature so characteristic of the structure of East Siberia and Manchuria.

Chalk and Tertiary deposits are widely spread. They constitute the bottom of nearly all the basin, and reach a thickness of 2000 feet in Ferganah, and 5000 feet in the Hissar region. Two systems of dislocation are pretty well observed amidst these deposits which are folded in two chief directions: north-east (60°) and north-west (60°). This observation of M. Moushketoff is well worthy of notice. We thus find, on the outskirts of the hilly tracts of Asia, the two great systems of upheavals which are so characteristic of Asia: the system of ridges and plateaux running from south-west to north-east, which we have found appearing with such persistency in the East Siberian hilly tracts; and the north-western direction, which appears predominantly in South-West Asia.

The Chalk deposits show great variety of structure: sandstones, limestones, and marls predominating. As to their fossils, they appear at some places in immense masses, but the number of species is mostly limited. According to M. Romanovsky, the Upper and Middle Chalk are represented there: the former, very rich in oysters, is closely akin to the Senonian of Europe; it is much developed on the outskirts of the Tian-Shan, especially in Ferganah, but it changes its characters (Senonian Ammonites making their appearance) farther west, in the lower parts of the Amu-daria. The Middle Chalk, which, however, it is difficult to separate from the former, has a still wider extension. The Chalk contains a number of useful minerals; namely, phosphorite, gypsum, naphtha, ozokerite, and sulphur.

The Tertiary deposits are so closely connected with the Chalk deposits that it is often difficult to separate them from one another; they are still poorer in fossils (excepting those on the northern and western shores of Lake Aral, as yet unexplored), especially towards the east, as we approach the Tian-Shan. In this last region we have, as is known, the Eocene deposits, consisting for the most part of deep-sea deposits of Nummulite sandstones. They are covered with Lower and Middle Oligocene, very much like the German and Belgian Tertiary deposits, and these last in their turn disappear under Miocene limestones and Sarmatian clays.

The Tertiary deposits of the Tian-Shan contain, on the contrary, very little or no clays, and chiefly consist of conglomerates and sandstones. Some of them date from

the Eocene period, some others from the Oligocene; while the most recent Miocene and Pliocene deposits contain a fauna in process of decay: the deep-sea fauna of the banks of the Aral is substituted by a shallow-water fauna, and the Nummulite banks disappear. The chief fossils are teeth of sharks, some Lamellibranchiata, and a few oysters (*Sphenia rostrata*, Lamk.; *Modiola subcarinata*, Lamk.; *M. jeremejewi*, Roman.; *Alligator darwini*, Ludw.; *Ostrea raincurti*, Desh.; *O. longirostris*, Lamk., &c.). These features, as also the extension of pudding-stones, especially on the outskirts of the Tian-Shan, are indicative of their littoral origin. The same distinction appears as to the minerals they contain. Several great beds of gypsum, brown-coal, and bituminous slates are found in the Tertiary deposits around Lake Aral, as also naphtha in the Balkhan mountains; but both naphtha and brown-coal are absent in the Tian-Shan deposits, which contain, on the contrary, salt, together with gypsum.

The Post-Pliocene Aral-Caspian deposits can hardly be delimitated from the Tertiary deposits. Their maximum thickness does not exceed 100 feet. Both in the Black-Sands (Kara kum) and the Red-Sands (Kyzyl-kum) they consist of a sandy clay which often passes upwards into a clayey sandstone. As to their petrographical features, they are the same from the Volga to the foot of the Tian-Shan. The fossils they contain (*Cardium edule*, *Dreyssena polymorpha*, *Neritina liturata*, *Adacna vitrea*, and *Hydrobia stagnalis* in the Kara-kum; *Lithoglyphus caspius*, *Hydrobia stagnalis*, *Anadonta ponderosa*, and the Spongia described as *Metschnikowia tuberculata* by M. Grimm in the Kyzyl-kum) are all now living in the Caspian and Lake Aral, and precisely in the littoral shallow-water zone.

What are the limits of this immense Post-Pliocene basin surely forms one of the most interesting problems of geology, and they can already be determined approximately. In the west, the Ergeni hills (which run due south of the great Tsaritoyn bend of the Volga) form its western shore[1]—a great gulf extending along the broad valley of the two Manych rivers towards the Black Sea. Further south it must have been much nearer to the present shore of the Caspian, with a broad gulf to the west in what is now the valley of the Kura. How far this gulf extended towards the north remains still unsettled. The evidence derived from the *Dreyssena polymorpha*, found as far north as the Samara winding of the Volga, is still contested by MM. Möller and Grimm—this species of *Dreyssena* being a too cosmopolitan one; but the discovery of a few Caspian mussels even further north, towards Simbirsk, as well as the orography of this region, make one incline to the opinion that a narrow gulf of the Aral-Caspian Post-Pliocene sea extended almost as far as the mouth of the Kama, with a wide lake filling up the Oka depression of the Volga and communicating with the sea by an outlet. It is known that this basin extended towards Lake Aral and further east, with a peninsula which entered it from the north, and which is now known as the Ust-urt and Mugo-djar hills. How far it extended towards the east remains still unsettled. M. Moushketoff only mentions the supposition of the late M. Severtsoff as to the connection which existed between Lake Aral and Lake Balkhash. However probable this connection, we ought to take into consideration the latest researches of Russian zoologists, according to which the fauna of Lake Balkhash would have much more kinship with the lakes of Central Asia than with the fauna of Lake Aral. If this fact is confirmed, we should probably distinguish two different periods—an earlier and a later one—during which last the connection between Lake Balkhash and Lake Aral was broken, but continued between the former and the eastern lakes of Central Asia.

[1] Prof. Barbot-de-Marny, whose deep insight and keen observation are so highly esteemed, extended these limits further west. Several considerations derived from the orography and physical geography of the region give, in my opinion, great probability to M. Moushketoff's view on the question. He has also had the opportunity of making a more thorough exploration of the region.

As to the southern limits of the Aral-Caspian basin, they cannot yet be determined with certainty. Aral-Caspian deposits are wanting in the middle parts of the Kyzyl-kum plateau, so that the southern shores of this basin must have been somewhere in the latitude of the Bukan-tau mountains. Further east they ran in a more southern latitude In the Sary-kamysh depression and for 160 miles further south we again find Aral-Caspian mussels, as far as the Bala-Ishem wells, and in this region the Uzboy (formerly considered as the old bed of the Amu) disappears. South of Lake Aral they hardly reach the latitude of Merv. From all these data, M. Moushketoff concludes that the basin consisted of two different parts—the Caspian and the Aral part—connected by a narrow outlet passing by the base of the Balkhan mountains. The eastern portion was shallower than the western; it had more islands, and its organic life was poorer. It was also subdivided, in its turn, into two parts connected by the Aibughir outlet.

As to the drying up of this basin and its subsequent modifications, which M. Moushketoff attributes in great part to the agency of the wind, we shall devote to them a second article, inasmuch as the author's observations on the dunes and moving sands deserve special attention.

P. K.

(*To be continued.*)

THE NATURALIST'S DIARY

The Naturalist's Diary. Arranged and Edited by Charles Roberts, F.R.C.S., L.R.C.P., &c. (Swan Sonnenschein, Le Bas, and Lowry, Paternoster Square).

THIS book may be described as a most excellent *vade mecum* and guide to any person who not only wishes to keep a phenological diary, but who wishes to know what to enter therein. The preface and introduction show forth the principles which have guided the author in making this compilation, and the important services it may be made to render to biologists and to men of science, as well as to practical gardeners, agriculturists, sportsmen, and residents in the country generally. It is also recommended to the notice of tourists, and especially to those who find themselves perchance perforce anchored in some one of our numerous health resorts, cut off from their usual avocations. Mr. Roberts's observations have been made on the breezy downs of Marlborough in connection with the Marlborough College Natural History Society, 1864–84. They include registration of mean, maximum, and minimum temperature in sun and shade, "accumulated temperature" above 42° day degrees, barometrical observations, rainfall, and direction of wind.

These are, however, only the necessary key to what follows in the most interesting observations upon the first appearance of each familiar flower, the maiden song of each sweet warbler of the grove, the arrival of summer visitants, such as the swallow, swift, corn-crake, or cuckoo, and the emergence of insect, reptile, fish, or hibernating mammal from winter's sleep.

The student is provided with a series of 365 pages, fittingly and instructively introduced, one being devoted to every day in the year. Each page is numbered both prospectively and retrospectively, showing not only the number of days or pages from the beginning, but to the end. These pages are partly blank, and upon the left-hand side the reader is told what to look for in the vegetable or animal kingdom, what flower may be expected to raise its head, or, as the season advances, what fruit may be expected to ripen. We are almost all of us keenly alive to the interest of watching the unfolding season, and a book of this kind embodying information already obtained, and inviting the reader to record his own observations on the same points, must commend itself to a large class of persons. Take as an example p. 133, or the 133rd day of the year, May 13, and we find that we should on this day "look out" for the green hair-streaked butterfly, the light tussock and rivulet moths, and the egg of the lesser whitethroat; we may also look for the spindle-tree in flower and the common mallow, although somewhat before their usual times. The blossom of the whitethorn, which is always known as "May," has been seen at Marlborough on April 30, and again has not been seen till June 4, information which is thus succinctly set forth, "*Cratægus oxyacantha*, 120-155, Hawthorn, Whitethorn, May," the figures indicating the earliest and latest days of the year upon which this favourite flower has been known to bloom.

There appears, indeed, to be no limit to the kind of things which an earnest student of Nature might not pleasantly note as affording material for his *Naturalist's Diary*. And so wide is now the net thrown, and so extraordinary are the correlations of science, that no fact need be passed over as unworthy of notice. For example, we are told in the introduction that "closely connected with the subject of migration, and equally deserving of systematic observation, is the congregation or flocking of birds in the autumn and winter months, as it is probably correlated with hibernation of fishes and reptiles." So that watching the loves of doves, and packing of partridges, listening to the early soft cooings of pigeons, or the crow of the pheasant, chronicling the advent of the cuckoo, or of "sweet Philomel complaining," or listening to the first strains of that "rapture so divine" which the immortal Shelley ascribed to our most sustained songster—in each case we may by accuracy of observation add a drop to the ocean of facts slowly developing into universal knowledge. Such a task could not fail of being attractive. Possibly it may tend to dissipate the sweet and more dreamy influences which steal over us insensibly while experiencing the gradual unfolding of Nature—the feeling so tenderly expressed by Longfellow in his exquisite prelude to the "Voices of the Night"; but this awakening from the poetic dream appears to be the fate of communities as well as of individuals, and we must, we suppose, resign ourselves to it. It is the province of science to ransack, to dissect, to arrange, to chronicle, and not to "babble o' green fields" only, as Dame Quickly said of poor Sir John Falstaff lying a-dying.

Downton, May 12 JOHN WRIGHTSON

OUR BOOK SHELF

Scientific Results of the Second Yarkand Mission, based upon the Collections and Notes of the late Dr. F. Stoliczka. "Araneida." By the Rev. O. P. Cambridge, M.A. (Published by order of the Government of India, Calcutta, 1885.)

WE have already on several occasions noticed the memoirs published by the Government of India on the collections made during this expedition to Yarkand. The spiders were placed in the very capable hands of the Rev. O. P. Cambridge for description. The collection cannot be considered as fairly representing the fauna of the extensive region traversed during the expedition, an area which Mr. Hume thinks might be subdivided into five well-marked regions, but which the author, judging from the collection of Araneida, conceives might have been well considered as but two: that is, (1) from Murree to Cashmere, including the latter as well as the former; and (2) the whole of the rest of the area travelled over by the Expedition, and comprising the neighbourhood of Leh, the route from Tantze to Chagra and Pankong Valley, and from Yarkand to Bursi, as well as Yarkand and neighbourhood, Kashghar, the hills west of Yarkand, and the Pamir.

In the former of these more than half of the whole number of spiders were collected—69 out of 132. The leading character of these is European, with a few more distinctly tropical and sub-tropical species. The character of the latter region is also European, but with decided sub-Alpine features, and scarcely a trace of any even sub-tropical form; and of the 69 species met with in the former three only were found in the latter, and only one, *Drassus dispulsus*, occurred throughout.

Of the 132 species, 23 seem identical with European species already described, leaving the large proportion of 109 as apparently new to science. Even this number cannot be supposed to represent the new species in the fauna of this region. The season of the year was very much against the success of the collection, and the hands of the collector were very much engaged with other branches of natural history; and there can be no doubt that a large harvest awaits the explorer of the southern slopes of the mountain regions of Cashmere, where the tropical character of the forms will become more marked; and probably a still greater diversity in the species will be found in those from the more central regions of India. For comparison upon these points the author regrets that there exist no materials, for almost nothing has as yet been published about the spiders of tropical India.

Two quarto plates with 21 figures of the more important new species accompany this Report.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Thomson Effect

I AM indebted to Dr. Everett for calling my attention to the confusion which has crept into § 193 of my book on "Heat." I had not noticed it; but, happily, it can easily be removed. Take to the end of the section the statement quoted by Dr.

Everett; and delete the word "Thus" in the sentence which, at present, (wrongly) follows instead of preceding it. This change is obviously called for by the context:—for the reader has just been told how far *theory* had guided Thomson as to certain "absorptions," &c., of heat; and, of course, expects next to be told what additional information, as to these "absorptions," &c., Thomson obtained by *experiment*.

Still, confused as it is, the passage could not (except possibly from the point of view of history) embarrass a reader of § 196; for the nature of the Thomson effect is there *again* clearly stated, and even illustrated by a diagram. [A much more serious case of confusion is to be found at p. 366, line 15; where (by the omission of a few words) my copyist has made absolute nonsense of a quotation from Clerk-Maxwell.]

The statement quoted by Dr. Everett obviously requires to be restricted, as follows:—

An electric current, passing from cold to hot in copper, behaves as a real fluid would do:—i.e. *it tends to reduce the gradient of temperature. In iron, under the same circumstances, it tends to increase the gradient.*

It is clear that this statement has nothing to do with the *general* nature of the Thomson effect:—*i.e.* "absorption" or "disengagement" of heat:—for *this* would depend upon the temperature of the fluid spoken of. It raises the question of the excess of Thomson effect in one locality, over that in another, at a lower mean temperature but with an equal gradient.

Dr. Everett seems to forget that, though the water-equivalent of a metal may be treated as sensibly constant through moderate ranges of temperature, the "specific heat of electricity" cannot so be treated. Using his notation, (with the proviso that θ is *absolute* temperature) we have $\sigma = k\theta$, and the equation he quotes from Thomson is

$$\frac{d\theta}{dt} = -\frac{k\theta}{c}\frac{d\theta}{dx}.$$

Happily, this can be integrated, so that we have

$$\theta = F\left(x - \frac{k}{c}t\theta\right) \; . \; . \; . \; . \; . \; . \; . \quad (1)$$

Now suppose the gradient of temperature to be uniform and positive along x positive (the direction of the unit current); when $t = 0$ we have

$$\theta = ex.$$

Generally, therefore,

$$\theta = e\left(x - \frac{k}{c}t\theta\right),$$

$$= \frac{ex}{1 + \frac{k}{c}et}.$$

Thus the gradient becomes less steep:—*i.e.* there is a tendency to reduce temperature differences, when k is positive, as in copper. In iron, where k is negative, the tendency is to make the gradient steeper:—*i.e.* to exaggerate differences of temperature. Of course, as in all these thermo-electric matters, reversal of sign of the gradient reverses the thermal effect.

The general integral (1) denotes a process of continued *simple shearing*, not *translation*, of the "temperature curve." Were it not for heat-conduction, harmonic waves of temperature would tend to become *breakers*. But it is idle to speculate farther.

How much of this is Thomson's I don't certainly know; and I am for the present too busy to enquire. But it would be difficult to overestimate his services to Thermo-electricity.

This will, I hope, meet with Dr. Everett's approval. As to his letter, I would say (in Scottish legal phrase) "*Quoad ultrà*, denied."

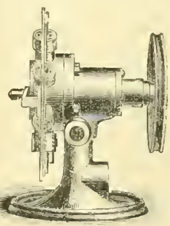
Power in Laboratories

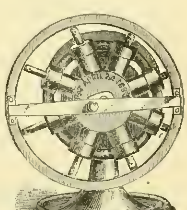
IN connection with the admirable devices for the distribution of driving-power in laboratories, illustrated in NATURE, vol. xxxiii. p. 248, the description of a novel and very effective form of water-engine, with which I have been experimenting for several months, will be of interest.

One of these motors is set up in the cellar of our science hall, where it is supplied with aqueduct-pressure of sixty pounds to the square inch, and the power is transmitted from it by means of rubber belting led over "idle pulleys" to the upper stories of the building, where a small engine-lathe and dynamo are driven. A word will suffice to explain the very simple construction of the motor—a system of radial cylinders, with their bases at the centre of the motor, through which runs the driving-shaft. The pistons in these cylinders are single-acting, and the water is admitted to them in succession by the rotary valve which forms part of the main shaft. The pistons, thus, in pressing outward, exert their force against a strong ring, to which is bolted a cross-bar which engages the crank of the main shaft. Thus the ring, in turning the shaft, has the vibratory motion of an eccentric, and returns the opposite pistons to the bases of the cylinders, at the same time exhausting the water through the interior of the rotary valve. Three pistons are thus constantly exerting a thrust upon the ring, whatever its position, and this thrust being always tangential to the arc of revolution of the crank, there is no "dead centre," and the uniform pressure at right angles to the crank at every part of its arc insures an even rotary motion and obviates the necessity of a balance-wheel. The ends of the piston-rods are slotted, and contain anti-friction rollers which bear against the ring, and this latter is grooved all round, so that, in addition to its simple and rapid motion as an eccentric, the ring is free to perform a slow motion of revolution independently of its work of driving the crank, and the wear of the interior face of the ring is thus equalised and becomes inappreciable.

The supply-pipe for this motor has a diameter of $1\frac{1}{2}$ inches, and it gives an equivalent of nearly 2 horse-power. The flow of water is regulated by means of a balanced valve, under control from every point where the power is used. As the use of the power is, for the most part, discontinuous, like that in lathe-work, I find it better to start and stop the motor as often as desired than to use the ordinary device of shifting a belt off and on a loose pulley. All possible economy of water is assured, as



Side View.



Front View.

none of it runs to waste without giving its equivalent of power at just the time when it is required. It will be seen that this form of motor is specially adapted to such uses, as there is no fly-wheel whose inertia has to be overcome; and as the motor has no "dead centre," it readily starts from any position, overcoming a maximum resistance.

Where continuous running is required, at an invariable speed, a centrifugal governor is attached to the belt-wheel, and acts upon the amplitude of vibration of the ring, diminishing the stroke of the pistons when the resistance is removed. The governor thus gauges the water-supply exactly proportional to the resistance to be overcome, and makes the motor a very effective driving-power for dynamos and all sorts of machines and apparatus in which a uniform speed is necessary, while the resistance is variable.

The difficulties barring the economic use of water as a motive-power, owing to its weight and incompressibility, seem to have been successfully overcome in this form of motor, with which unexampled speeds have been attained, and more than 80 per cent. of the theoretical power of the water derived. The little cut annexed shows the smallest size of these motors—it stands about 10 inches high, and uses a $\frac{1}{2}$-inch supply, consuming less than six quarts of water in 100 revolutions. I frequently run it at a speed of 1000 revolutions to the minute, and at the manufactory I have seen the same motor attain double this velocity. The motor runs equally well with compressed air (or with steam, if the piston-packings are changed), and with either of these media even higher speeds are attainable.

I find that the constant readiness of the motor for the immediate development of power, the little care it has required (only occasional oiling), and its economical consumption of water, are

very great advantages in its favour; and, for all laboratories supplied with aqueduct-pressure, I venture to think that it affords the best solution of the problem of inexpensive, convenient, and effective power. DAVID P. TODD

Lawrence Observatory, Amherst, Mass., May 15

Scientific Nomenclature

IN a letter published in NATURE for May 27 (p. 76) Prof. Minchin proposes to replace the expression "potential energy" by "static energy." It seems to have escaped his notice that a similar expression, proposed many years ago by Sir William Thomson, was used until it was replaced by the very words which Prof. Minchin wishes now to abolish. A short account of the question is given by Maxwell in "Matter and Motion," p. 81, and I should like to bring the following passage to the notice of those who take an interest in this question:—

"This is called the 'sum of the tensions' by Helmholtz in his celebrated memoir on the 'Conservation of Energy.' Thomson called it statical energy; it has also been called energy of position; but Rankine introduced the term potential energy—a very felicitous expression, since it not only signifies the energy which the system has not in actual possession but only has the power to acquire, but it also indicates its connection with what has been called (on other grounds) the potential function."

Harrow, June 8 G. GRIFFITH

Neæra

I WISH to request any of your readers who may dredge, or have opportunity this summer, to observe living or fresh specimens of the genus *Neæra*, Gray, and see whether branchiæ exist in that group. A Lamellibranch without branchiæ is anomalous, to say the least. I find in a new species of *Neæra* (sub-genus *Myonera*) from the Gulf of Mexico the following anatomical facts:—The mantle closed except for the small siphon and a narrow short slit for the thorn-shaped foot; no gills, no palps; the oral opening circular, plain; the roof of the peripedal cavity between the base of the body and the mantle margin is flattish, fleshy, with sparse pustules; a peripheral very stout pink muscle runs on each side around this, and is prolonged upward to the shell before the true adductor at each end of each valve, thus accounting for the double scars to be found there; the foot is close to the oral orifice, not grooved for the byssus, but pedunculated and surrounded by a groove; around the siphonal opening are numerous tentacular processes and a moderate number of ocelli. The specimens appear to be adult and perfectly preserved. An examination of specimens of *Neæra arctica* and *Neæra obesa*, Lovèn, indicated a similar state of affairs, though these specimens were not in as good condition as the one from the Gulf of Mexico. I do not find in the literature any categorical statement of the observation of gills in this genus. Clark is non-committal (in his "British Testacea"), Jeffreys speaks of seeing the "pink gills" through the shell, but that which he saw *pink* was without doubt the circular muscle I have mentioned.

The question is worthy of a definite solution. My specimens seem to leave no doubt that there are no gills, but it is always best to be suspicious of material long in alcohol.

"Plants and their Defences"

WITH regard to the interesting article in your issue for May 6 (p. 5) on "Plants and their Defences," I should like to offer two remarks, and in return would be very glad to receive from you information upon a certain point. (1) The author enumerates different species of plants protected by the severe stings of ants, but does not seem to know the remarkable work of Beccari, "Piante ospitatrici ossia piante formicarie della Malesia e della Papuasia" (Malesia, vol. ii., Firenze, 1885). Beccari describes seventeen partly new species of "Myrmecophilous" Rubiaceæ, among which are eleven of Hyd*n*ophytum (not Hyd*ro*phytum, as is erroneously given in the article in NATURE). You will find a further contribution to this question in Henry O. Forbes's "Wanderungen durch den Malayischen Archipel," vol. i. pp. 84-88 of the German translation.

For my part, I should be greatly obliged if you would communicate to me the title of the original work from which the author of "Plants and their Defences" has taken his account of *Triplaris Schomburgkiana*, *Schomburgkia tibicinis*, and *Acacia sphærocephala*.

(2) Concerning the same article, Mr. Alfred W. Bennett (NATURE of May 20, p. 52) is inclined to think that the poisonous fluid of the nettle-glands is not formic acid, as generally conjectured, because the fluid frequently has an alkaline reaction. As a matter of fact, Prof. Dr. Haberlandt, at Graz (Austria), has recently, in vol. xciii. of *Sitzungsberichte des kaiserl. Akademie der Wissenschaften in Wien*, 1886, Februar-Heft, shown in his article, "Zur Anatomie und Physiologie der pflanzlichen Brennhaare," that (1) the poison of the stinging glands is not identical with formic acid; (2) nor is it the albumen dissolved in the fluid of the glands; but (3) that most probably this fluid is a transformed ferment or enzymotic poison.

Frankfurt a. Oder, June 2 E. HUTH

A Remarkable Hailstorm

ON April 17, at 4 o'clock p.m. (local time), a very remarkable hailstorm visited the neighbourhood of a small hamlet, called *El Totumo*,[1] not far from the town of Tinaco, section Cojedes, State of Zamora, Venezuela. The place is approximately in 9° 25′ N. lat., and 68° 5′ long. W. of Greenwich, certainly not more than 200 metres above sea-level. My informant is a resident of El Totumo, named Nicolas Moreno Nuñez, who is universally said to be a trustworthy and respectable man. There was first a very heavy thunderstorm with much rain; but after some time hailstones began to fall in such abundance that it might have been easy to collect them by hundreds of bushels, some weighing as much as two ounces. It is well known that between the tropics hailstorms are exceedingly rare in localities situated in the lowlands; but the present case is still more interesting, on account of the colour of the hailstones, some of which were *whitish, whilst others were blue or rose-coloured*. I have read of but one instance in which the two last-mentioned colours were observed, viz. in the hailstorm of Minsk of June 14, 1880, described by Lagunowitch, and quoted by Th. Schwedoff in his memoir "On the Origin of Hailstorms."[2] Schwedoff thinks that the blue and rosy colours are owing to the presence of salts of cobalt and nickel, and thus confirm his hypothesis of the cosmic origin of hail. I do not know whether the existence of those mineral constituents in the hailstones of Minsk was ever made certain by chemical analysis, and it is of course impossible for me to do so in the present case, when almost a month has passed since the phenomenon took place. But it is undoubtedly a very curious coincidence that the *same* colours should have been observed in both instances and in localities so widely separated from each other; whilst there is not the slightest possibility that my informant, an honest and plain countryman of no literary education whatever, should have had any knowledge of such an observation having been made before.

Caracas University, May 12 A. ERNST

[1] This is the vernacular name of the calabash-tree (*Crescentia Cujete*); there is, or was, probably a remarkable specimen of this tree in the neighbourhood of the hamlet.

[2] I only know a Spanish translation of Schwedoff's memoir, in *Crónica científica* (Barcelona), 1882, No. 120, pp. 553-60.

VISITATION OF THE ROYAL OBSERVATORY

THE visitation to the Royal Observatory by the Board of Visitors took place last Saturday, when there was a very numerous attendance. The report of the Astronomer-Royal to the Board gives, as usual, an account of the work done during the past year, and references to any points of interest or importance which have been raised. From the report we select the following particulars:—

Mr. Turner has recently investigated the discordance between observations for coincidence of the collimators made respectively through the apertures in the cube of the transit-circle and with the instrument raised. A wooden model of the cube was constructed through which the observation could be made when the transit-circle was raised, and it was thus shown that the discordance was due to the cutting off of portions of the object-glasses by the cube, and not to any effect of temperature. In view of this result it seems desirable that the optical

definition of the collimator object-glasses should be thoroughly tested.

A discussion of the collimation-observations made throughout the year 1885 with the reversion-prism shows that for the regular observers the personality depending on the apparent direction of measurement is extremely small. Any possible effect of the kind is eliminated by the method of observation adopted with the reversion-prism. The personality depending on the direction of motion, as deduced from the results of reversed and ordinary transits of clock-stars with the reversion-prism, appears to be more decided, though the amount is small except in the case of one observer.

The personal equation instrument was completed last autumn, but was dismounted during the winter to preserve it from injury in the bad weather. Series of observations have been taken with it on five days, and the results appear to be very satisfactory, the accordance being as close as could be expected. The absolute personal equations thus obtained seem to show that all the observers observe too late, the differences between the several observers agreeing well with the relative personal equations found from observations of clock-stars.

The sun, moon, planets, and fundamental stars have been regularly observed during the past year, together with other stars from a working catalogue containing about 2750 stars. Good progress has been made in the observation of these stars, in view of the formation at the end of 1886 of a Ten-Year Catalogue, epoch 1880·0. The annual catalogue of stars observed in 1885 contains about 1250 stars.

The following statement shows the number of observations made with the transit-circle in the twelve months ending 1886 May 20:—

Transits, the separate limbs being counted as separate observations	5685
Determinations of collimation error	306
Determinations of level error	332
Circle observations	5133
Determinations of nadir point (included in the number of circle-observations)	318
Reflection-observations of stars (similarly included)	530

The value found for the co-latitude from the observations of 1885 is 38° 31′ 22″·04, differing by 0″·14 from the assumed value; the correction to the tabular obliquity of the ecliptic is + 0″·81; and the discordance between the results from the summer and winter solstices is − 0″·98, indicating that the mean of the observed distances from the pole to the ecliptic is too great by + 0″·49.

The mean error of the moon's tabular place (computed from Hansen's Lunar Tables with Prof. Newcomb's corrections) is + 0·02s. in R.A. and + 0″·36 in longitude, as deduced from 105 meridian observations in 1885. The mean error in tabular N.P.D. is − 0″·58, which would appear to agree with the observations of the sun in indicating that the mean of the observed N.P.D.'s is too great.

The observations of the moon with the altazimuth have, as usual, been restricted to the period from last quarter to first quarter in each lunation, the total number of observations of various kinds made in the twelve months ending 1886 May 20 being as follows:—

Azimuths of the moon and stars	213
Azimuths of the azimuth-mark	146
Azimuths of the collimating-mark	176
Zenith-distances of the moon	110
Zenith-distances of the collimating-mark ...	172

The reversion-prism has been used during the past year with the altazimuth for investigation of the personality depending on the apparent direction of motion of stars or the moon. The plan adopted has been to observe a transit over the first three wires with a certain apparent direction of motion and over the last three with the apparent direction of motion changed. A second transit is then observed with the conditions reversed, so that in each double transit there are two sets of observations over the same six wires with the apparent direction of motion different, from which a determination of the personality is obtained by simple subtraction without any calculation of intervals of wires. The results show that the personality is in every case small, and that further observations are required to separate it from accidental errors of observation.

A clock synchronised by hourly currents, on Lund's system, has been presented to the Observatory by the Standard Time and Telephone Company, and is fixed in the Astronomer-Royal's office.

A new plane mirror (silver on glass) has been obtained from Mr. Calver for the Lassell equatorial, and a wooden screen has been fixed at the eye-end to protect the open end of the tube from the heat of the observer's body, it having been found that the definition was much affected by convection-currents at the eye-end, giving rise to an apparent astigmatism which was at first supposed to be caused by tilt of the large mirror. The optical performance appears now to be satisfactory. At Mr. Common's suggestion a frictional connection between the clock and the driving screw has been applied so as to allow of the latter being turned in either direction (for slow motion in R.A.) without putting the clock out of gear.

For determination of motions of stars in the line of sight, 378 measures have been made of the displacement of the F line in the spectra of 51 stars, and 21 measures of the *b* lines in 8 stars, besides measures of the displacements of the *b* and F lines in the spectra of Mars and Venus, and of the east and west limbs of Jupiter, and comparisons with lines in the spectrum of the moon, or of the sky, made in the course of each night's observations of star-motions, or on the following morning, as a check on the general accuracy of the results. The observations of Sirius during the past twelve months indicate, as in the last three years, a displacement of the F line towards the blue (corresponding to a motion of approach), the amount being slightly larger than in the preceding year. Spectroscopic observations were interrupted on a number of nights through deficient supply of water for the driving-clock of the south-east equatorial. After some correspondence with the Kent Waterworks Company it was arranged that the pressure in the Observatory main should not be reduced to so low a point in the evening, and no further trouble with the water supply has been experienced since. The experiments with the reversion spectroscope of the Oxford University Observatory (lent by Prof. Pritchard) indicate that this form of instrument is well adapted for observation of displacements, provided certain improvements can be effected in the optical and mechanical parts.

For the year 1885 Greenwich photographs are available for measurement on 208 days, and photographs from India and the Mauritius, filling up the gaps in the series, on 152 days, making a total of 360 days out of 365 on which photographs have been measured. The record has thus been made practically complete for 1885 by means of the Indian and Mauritius photographs.

A table of the means of daily areas of spots and faculæ and of the mean heliographic latitude of spots has been formed for each synodic rotation of the sun, and for each year from the commencement of the Greenwich series in 1873 to the end of 1885.

Further experiments for determination of the temperature corrections for the horizontal and vertical force magnets by alternately warming and cooling the basement on successive days were made in the spring of this year, a continuous record of the temperature being obtained by means of the Richard thermograph. The following are the results thus obtained in 1885 and 1886 as compared with the previous determinations, the appa-

rent changes for 1° of temperature being expressed in terms of the horizontal force and vertical force respectively:—

For 1° Fahr. increase of temperature	1869	1885	1886
Apparent decrease of horizontal force	·00018	·00026	·00021
	1882	1885	1886
Apparent increase of vertical force ...	·00020	·00022	·00020

The following are the principal results for magnetic elements for 1885:—

Approximate mean declination 18° 2′ west.

Mean horizontal force... ... { 3·9376 (in English units). 3·8156 (in metric units).

Mean dip ... ... { 67° 27′ 28″ (by 9-inch needles). 67 27 32 (by 6 inch needles). 67 28 27 (by 3-inch needles).

In the year 1885 there were only three days of great magnetic disturbance, but there were also about twenty days of lesser disturbance for which it may be desirable to publish tracings of the photographic curves. It is proposed to add tracings of the registers on four quiet days to serve as types of the ordinary diurnal movement at four seasons of the year, as was done for 1884.

The automatic drop of the Greenwich time-ball failed on two days during the past twelve months, on one occasion through accumulation of snow on the mast, and on another through failure in the clock-work apparatus for daily reversal of the currents through the electro-magnets. This apparatus has since been removed, and the direction of the currents is now reversed by hand once a week. On one day the ball was not raised on account of the violence of the wind.

As regards the Deal time-ball, there have been seven cases of failure owing to interruption of the telegraphic connections, and on three days the violence of the wind prevented the raising of the ball. There have been three cases of failure of the 1 p.m. signal to the Post Office.

No further action has been taken as regards the establishment of hourly time-signals at the Lizard or Start, as the arrangements for preliminary trial of a collapsible cone at Devonport are not yet completed. One of the Transit of Venus clocks (Dent 2010) has been adapted by Messrs. E. Dent and Co. to give hourly time-signals, and to be synchronised by the help of an auxiliary seconds' pendulum on the plan I proposed in the last report.

The longitude of Gibraltar was determined last year under Capt. Wharton's direction, by exchange of telegraphic signals on August 8, 9, and 12 between Greenwich and Gibraltar, the Eastern Telegraph Co. having courteously given the free use of their telegraph cable for the purpose. The signals were transmitted by relay-action from the ends of the cable to the observing-stations at Greenwich and Gibraltar. Local time was determined at Gibraltar by the officers of H.M.S. *Sylvia* with the sextant, and at Greenwich by Commander Moore and Lieut. Douglas by means of sextant observations, and also by transits with the transit-circle. In connection with this determination a large number of observations of signals were made at Greenwich for the determination of the personal equations of the different observers in observing telegraph signals. At Greenwich the longitude signals were observed by five observers independently. Commander Moore and Lieut. Douglas made a series of observations at Greenwich last summer for comparison of the relative value of determinations of local time made with a sextant and with a small transit instrument respectively.

The record of the past year shows that the work in all branches tends to increase. This increase could not well be resisted without impairing the efficiency of the Observatory, but year by year it causes more pressure on our limited staff, which, in addition to scientific work, is charged with the ever-increasing duties of a Government Office. In this connection I may mention that a good deal of my own time, as well as that of the Chief Assistant, has lately been occupied with various matters connected with the Navy, reference having been made to me on the subject of gun-directors, mirrors for electric search-lights, and binoculars, in all of which there are involved questions requiring careful consideration.

Commencing with the year 1885, Greenwich civil time, reckoning from midnight to midnight and counting from 0 to 24 hours, has been adopted in the spectroscopic and photographic results as well as in the magnetical and meteorological. It is proposed to defer the introduction of this time-reckoning into the astronomical results till the year 1891, for which year the Board of Visitors have recommended its adoption in the *Nautical Almanac*. In an Observatory such as this, where observations of various classes are carried on, there is, however, considerable inconvenience in the retention of the present astronomical day, which now involves the use of two systems of reckoning mean solar time in the same establishment.

The construction of an object-glass of 28 inches aperture and of 28 feet focal length, with suitable tube, to be mounted on the south-east equatorial, has been authorised by the Government, and the necessary funds have been provided in the estimates. The work has been intrusted to Mr. Grubb, with whom I have arranged the details of the tube, which is to be of special construction, adapted to the conditions of the mounting, and available for spectroscopy and photography as well as for eye-observations. Mr. Grubb proposes to provide means for readily separating the lenses of the object-glass to such a distance as will give the proper correction for photographic rays. Messrs. Chance are engaged in the manufacture of the glass for the lenses, and have already made a flint disk which promises to be very satisfactory.

In view of the recent development of astronomical photography, I propose to have constructed, for use with the present 12¾-inch refractor of the south-east equatorial, a combination of a convex flint and concave crown lens, which, when placed about 2 feet within the focus, would correct the chromatic aberration of the object-glass for the photographic rays without alteration of the focal length. If this plan succeeds, the instrument would then be well adapted for photography, thanks to the firmness of its mounting and the excellence of its driving-clock.

THE PAST WINTER

AT the meeting of the Royal Meteorological Society held on May 19 a paper was read on "The Severe Weather of the Past Winter, 1885-86," by Mr. C. Harding, F.R.Met.Soc. The paper dealt with the six months from October to March in a general way, and with the three months from January to March more in detail, as the latter embraced the period during which the weather was most severe, and in which both frost and snow were exceptionally prevalent. The material used in the discussion was for the most part contributed by the kindness of the Meteorological Council.

The greatest deficiency of temperature throughout the winter occurred in the weeks ending January 25, March 1, 8, and 15, the defect on the average amounting to as much as 9° and 10° over the greater part of England. During the fortnight ending March 15 the mean temperature was below the freezing-point in the Midland Counties and in the north-west of England, and, considering the British Islands as a whole, the temperature was lower during this fortnight than in any similar period of the winter. The means for each of the six winter months show that the temperature was below the average over the whole Kingdom in October, January, February, and March. In the east, south, north-west, and south-west of England, and the Channel Islands, as well as over the

greater part of the Midland Counties, and the north of Ireland, temperature was also below the average in December, whilst in the north-west of England and over a great part of the north of Scotland each of the six months was below the average. There was no part of the British Islands, except the Channel Islands, in which the temperature for each week, from the commencement of January until the third week in March, did not fall to the freezing-point or below, whilst in the south-west of England there was not a single exception after the first week in October, and in the east of Scotland, the north-east and north-west of England, the thermometer fell to 32° or below in each week from the commencement of November. The lowest shade-temperatures observed in the British Islands were: in January, − 2° at Braemar on the 19th, and 1°·1 at Alston on the 20th; in February, 2°·5 at Braemar and 7°·1 at Alston on the 5th; in March, − 2° at Alston and 1°·2 at Buxton on the 7th, and 2° at Braemar on the 12th. There were extremely few instances of the temperature falling below 5°; but temperatures below 10° were observed in January and March over the greater part of Great Britain.

From the commencement of January to the middle of March there was almost continuous frost, and during this period it froze for upwards of 60 nights at many places in the British Islands. At Great Berkhamsted the minimum temperature registered 32° or below in January 22 days, February 23 days, March 18 days, making a total of 63 days between January 3 and March 18; whilst on the grass it froze for 73 consecutive nights, from January 5 to March 18. At Cheadle in Staffordshire, Churchstoke in Montgomery, Llandovery in Carmarthen, and Great Berkhamsted in Hertfordshire, it froze for 33 consecutive nights, from February 14 to March 18, whilst at very many stations the frost continued 30 days or more. In Great Britain the longest period of frost occurred between the middle of February and the middle of March, but in Ireland it occurred generally in January. At Greenwich it froze on 28 consecutive days from February 19 to March 18; the observations from 1845 do not show another instance of frost continuing for so long a period without interruption. The only instances of 20 or more consecutive days are:—

24 days in 1858, from February 17 to March 12.
22 days in 1879, from November 20 to December 11.
21 days in 1855, from January 14 to February 3.
21 days in 1878, from December 6 to December 26.

For the three months from January to March there are but few years since 1845 that have a period of continuous frost of one-half the length of that in 1886. The years with fifteen days or more are respectively:—

1886 (28), 1858 (24), 1855 (21), 1861 (19), 1881 (16).

Taking the actual days with frost at Greenwich, irrespective of continuity, there was frost on 53 days in the present year (1886) from January to March. In 1855 the number of frosts in the corresponding period was 58, but the only other instance of more than 50 days was in 1858, when the number was 53.

Probably the most interesting feature in connection with the past winter was the excessively cold weather experienced over the whole country at the commencement of March. The Greenwich observations from 1814 only show two instances of a similarly low temperature—these were in 1814 and 1845. The unusual frequency with which snow fell was also a matter of interest, and the heavy drifts occasioned serious blocks on many of the northern railways.

The records of the London Skating Club show that there was skating on the Club water in Regent's Park on 38 days during the winter, and 1885–86 was the only winter in which there was skating in each of the four months from December to March since the formation of the Club in 1830, and the only March records of skating in the 56 years are 16 days in 1886, 12 days in 1844, 10 days in 1858, and 1 day in 1853. On a pond at Pinner there was almost continuous skating for 3 months, and and at Rickmansworth for about 70 days, but at both places the ice was most carefully nursed. On January 7 there was safe skating on snow-ice after one night's frost.

The temperature of the water in the Thames at Deptford was, on the mean, slightly in excess of the air. From January 8 to March 20 the entire range was from 40° to 34°; and from March 1 to 19 the maximum temperature was 36°·5 and the minimum 35°, showing a total range of 1°·5.

The recent temperatures observed at several stations over England show that at 1 foot below the surface the greatest cold for the winter was reached during the first 17 days of March. The mean was generally about 2° in excess of the mean air temperature. In January the earth temperature at 1 foot was from 2° to 3° below the average over the whole country, whilst in February it was from 4°·5 to 6°·5 below the average; the first 17 days of March, however, show a much larger defect on the average, the deficiency ranging from 6°·3 at Lowestoft to 8°·5 at Norwood. The temperature of the soil at 2 feet was generally about 2° in excess of that at 1 foot.

The logs of ships traversing the North Atlantic show that the abnormal conditions which prevailed over the British Islands and indeed over nearly the whole of Europe extended also a considerable distance to the westward. They show a decided tendency to a low barometer, during the early months of 1886, in the locality where a high barometer generally prevails, and to the north of this low barometer strong and persistent easterly winds were experienced. These facts tend to show a general reversal of conditions over the Atlantic which would doubtless be very intimately related to our own exceptional weather.

THE ASTRONOMICAL DAY

THE recently published report of the Science and Art Department contains some most important information showing what the recent Government action has been in relation to the resolutions passed at the Washington Conference.

The first letter that we need refer to is one from the Astronomer-Royal, in April last year, suggesting that reference should be made to various scientific Societies, in order to obtain an authoritative expression of opinion from the scientific men in this country interested in the question. This was followed by a meeting of the committee appointed to advise the Science and Art Department on the matter. The following resolution was adopted by the committee, which consisted of Prof. Adams, the Astronomer-Royal, General Strachey, Captain Sir Frederick Evans (since deceased), Captain Wharton (the Hydrographer), and Colonel Donnelly:—"The committee recommend that the report of the British Delegates to the Washington International Prime Meridian Conference, with the resolutions adopted by that body, be communicated to certain Departments of State, learned Societies, telegraph companies, &c., and that they be informed that the resolutions appear to be such as commend themselves for adoption; but before informing the American Government to that effect they would be glad to receive their opinions on the subject."

The Science and Art Department then addressed a letter to various public offices, scientific bodies, and telegraph companies. Their replies may be thus condensed.

The Eastern Telegraph Company, and the Eastern Extension, Australian, and China Company, state that they have always adopted the twenty-four-hour system in timing their messages, thus avoiding the necessity of signalling the letters a.m. and p.m.

The Society of Telegraph-Engineers and Electricians cordially approve of the first six resolutions of the Washington Conference, but they reserve their opinion as to the seventh (the one referring to the application of the decimal system to space and time).

The Royal Astronomical Society forwards the following resolution:—

"The Council of the Royal Astronomical Society desire to express their concurrence in the resolutions of the Washington Conference, and consider it desirable that the reckoning of astronomical time from mean midnight be adopted in the Nautical Almanac for 1890, the earliest practicable date, and that it be thenceforward adopted by astronomers."

The India Office writes that "the Government of India will be perfectly prepared to accept whatever conclusions may be arrived at by Great Britain after the discussions which will doubtless precede any final decision modifying the practice of astronomers, navigators, or others in this country in the reckoning of longitude or time."

The Board of Trade thinks that the resolutions are such as commend themselves for adoption.

The Royal Society forwards a report drawn up by a specially appointed committee, which the Council of the Society adopted:—

"The committee recommend the Council to approve of resolutions 1 to 6.

"With regard to resolution 6, if the change of time-reckoning be generally adopted, and can without inconvenience to mariners be made in the nautical almanacs of all nations for 1890, the committee recommend that year for the change to be made.

"With regard to the seventh resolution the committee would remark that, for astronomical reasons, the division of angular space is bound up with the division of time, and that a decimal division of the day would be opposed to the practice of, we may say, all nations, from very early times to the present day.

"Such a change the committee conceive ought not to be made without the gravest consideration. The committee observe, however, that the resolution does not appear to go beyond the expression of a hope that the subject may be further studied, to which of course there can be no objection."

The Eastern and South African Telegraph Company give the same reply as that given by the two Eastern Companies to which we have already referred.

The Submarine Telegraph Company does not adopt the twenty-four-hour system.

The Office of Works has no observations to make.

The Colonial Office has no objections to offer.

The views of the Admiralty were thus stated in a letter dated July 1885:—

"My Lords desire me to inform you that this question has engaged their attention since the receipt of the communication from the Science and Art Department of the 29th May, but that, seeing how many and varied are the interests involved in a proposal to make any alteration in methods of reckoning time which have for so many hundreds of years prevailed, they have thought it desirable, before offering any opinion, to obtain full information on the results which would follow, and the effect which it might have both on seamen and astronomers, more especially as the main responsibility of action would finally rest on their Lordships, as controlling the production of the Nautical Almanac.

"When their Lordships have received the report of the Board of Visitors to the Royal Observatory, Greenwich, who, as eminent astronomers, have been consulted, they will be in a position to give an opinion; but as they have been advised that that body cannot conveniently meet, without undue haste, until the autumn, their Lordships regret that, for the present, they cannot furnish any definite reply to the question asked by the Lords of the Committee of Council on Education."

The General Post Office letter states that there will be no objection to the adoption of a legally authorised system of counting time from zero to twenty-four hours, and that for some purposes it seems to possess advantages over the present system. The Postmaster-General is inclined to think, however, that, in the case of his Department in particular, the introduction of the system should depend upon popular feeling.

The Elder Brethren of the Trinity House see no objection to the immediate adoption of the sixth resolution, that as soon as may be practicable the astronomical and nautical days will be arranged everywhere to begin at mean midnight.

The above letters are given in the order in which they were received by the Science and Art Department.

In January of the present year, the Admiralty sent a second letter, which we give *in extenso*:—

"SIR, *Admiralty, 5th January*, 1886

"I am commanded by my Lords Commissioners of the Admiralty to inform you that they have had under their careful consideration your letter of the 29th May last, inclosing a copy of the resolutions passed by the International Conference for fixing a Prime Meridian and Universal Day, held at Washington in October 1884, and asking their Lordships' opinion thereon.

"2. The first five of these resolutions, causing as they do a minimum of change in the customs of this country, cannot but meet with their Lordships' unqualified approval, but do not appear to call for any action on their part.

"3. My Lords do not consider that the seventh resolution demands any remark from them.

"4. With regard, however, to the sixth resolution, which proposes a fundamental change in the mode of reckoning astronomical time, my Lords are deeply interested, not only so far as it may affect Her Majesty's Navy, but in consequence of the responsibility for the publication of the Nautical Almanac being vested by Act of Parliament solely in them.

"5. My Lords are of opinion that the sixth resolution may be regarded in two different lights:—

"1st. It may be considered as the natural corollary of the adoption of a universal time, such time being a civil day at the Prime Meridian; because, should universal time be adopted (for scientific and certain other purposes) the disagreement between civil and astronomical time, if retained, would to a great degree render nugatory the endeavour to introduce uniformity. In this aspect the change would seem to depend upon the adoption of universal time.

"2nd. This proposed change may also, however, be looked upon as intrinsically desirable in itself, besides as in a measure facilitating the adoption of universal time; and in this light action may be taken before any international consensus is arrived at with regard to universal time as recommended by the Washington Conference.

"6. Before, however, coming to any final conclusion on the advisability of sanctioning such changes in the ephemeris as would be necessary to give effect to this resolution, my Lords have felt bound to consult, both as to the principle and in respect of details, those other classes who habitually use the Nautical Almanac, viz., the mercantile marine and astronomers, as represented respectively by the Board of Trade and by the Board of Visitors to Greenwich Observatory, the latter being the most representative body of astronomers to whom my Lords could appeal.

"7. My Lords find that, while there is a general agreement in the desirability of putting an end to the present dual system of reckoning time, the urgency of the change is differently regarded by seamen and astronomers.

"8. Astronomers are now apparently finding many difficulties in the present duplication of time, and are desirous of a speedy change.

"9. At sea it causes but little practical inconvenience, as the two systems do not come into collision, being used for totally different purposes; and my Lords agree with the opinion expressed to them by the Board of Trade, that the change will not be unattended with risk from the possibility of mistakes during the period of transition, and that it must be made with all possible precautions.

"My Lords also fully recognise that the fact of the change rendering the existing epitomes and text-books of navigation to a great extent useless must receive due consideration from several points of view.

"10. It does not, however, appear to my Lords that there is sufficient reason to cause them to place obstacles in the way of making the change desired by British astronomers and many seamen, and recommended by the unanimous votes of the Delegates of the Washington Conference, as they consider that the rearrangement of the Nautical Almanac may be so carried out as to minimise the above-mentioned risks.

"11. My Lords will, therefore, be prepared to sanction such alterations in the Nautical Almanac as will be necessary to establish the change to the new reckoning at a date sufficiently far in advance to give ample warning to seamen.

"12. As, however, the fundamental objects in view of the Washington Conference were, to simplify and unify the modes of reckoning time, to remove present discrepancies, and to endeavour to establish an international system, it would appear that no decided move of any kind should be made until the views of other nations, and more especially those maritime powers which publish astronomical ephemerides, are ascertained. It would be manifestly contrary to the interests of simplification that England should alter the practice of centuries only to find herself alone in the new method of reckoning astronomical time; nor would it be courteous to announce her intention of so doing without consulting other Governments on the steps proposed by their representatives, but not plenipotentiaries, at the Washington Conference.

"13. My Lords will, therefore, be pleased to learn that the opinions and intentions of the other maritime nations have been ascertained at as early a date as practicable, in view of the wishes of British astronomers.

"I am, &c.

"(Signed) EVAN MACGREGOR.

"The Secretary, Science and Art Department,
"South Kensington, S.W."

After the receipt of the second letter from the Admiralty another meeting of the committee was held, and the following report was drawn up for the information of my Lords:—

"Your committee find that the Science and Art Department having consulted the various bodies named in the accompanying list, the first five of the resolutions of the Washington Prime Meridian Conference have received unanimous approval, but demand no action on the part of this country.

"As regards the sixth resolution, which proposes that as soon as may be practicable the astronomical and nautical days shall be arranged everywhere to begin at mean midnight, it appears that the opinion in England is generally in favour of this change in the mode of reckoning astronomical time, and that the Admiralty have expressed their willingness to take the necessary steps to give effect to this resolution of the Conference by introducing civil reckoning into the British Nautical Almanac, the rearrangement of which they are satisfied may be so carried out as to minimise risks from mistakes by navigators during the period of transition, if other maritime nations are prepared to adopt the proposed method of reckoning astronomical time.

"Under these circumstances your committee suggest that the Foreign Office be invited to communicate this result of the inquiries of the Science and Art Department to the Government of the United States, and to inquire whether, as conveners of the Washington Conference, they are now prepared to take steps to invite the adhesion of other maritime States."

Next follows a letter from the Science and Art Department to the Foreign Office, asking them to make the inquiry referred to in the previous report, and another from our ambassador at Washington, stating that the United States Government had taken the matter in hand.

FACILITIES FOR BOTANICAL RESEARCH

IN an article under the above heading, published in NATURE, vol. xxxi. p. 460, I endeavoured to draw the attention of our younger botanists to the importance of extending their studies over a wider field than is at present usual, and mentioned some easily accessible stations at which students might observe tropical vegetation. Since that article was written, I have had the opportunity of acting on my own suggestion, and of visiting Ceylon; I am therefore now in a position to enlarge upon my previous suggestions, and to fill in from personal experience many details which, though often trivial in themselves, may yet bring the possibility of Eastern travel home to the mind of some in such a way as may lead to future action. But while giving some account of the facilities for botanical work in the East, care must be taken not to over-colour the picture; it happens too often that writers of an enthusiastic bent raise expectations in the minds of their readers, which actual experience can only disappoint: in the following paragraphs I shall endeavour to make a purely matter-of-fact statement, and leave the colouring to be filled in at the will or opportunity of the reader. Taking first Peradeniya, we may consider what are its attractions as a station for botanical work, and then pass on to discuss the relative merits of other stations.

In the first place, hardly any port in the east is more accessible than Colombo: it has been aptly called the "Clapham Junction" of the East: the steamers of all nations meet there, and the competition between them produces a moderate scale of fares. Once there, a direct train service lands the traveller in about three hours almost at the gate of the Royal Gardens; the mechanical discomforts of many a journey to remote districts in the United Kingdom are greater than this. The cost of the journey will vary according to the line of steamers selected; by the Peninsular and Oriental line a return ticket can be had from London to Colombo for 90*l.*, 100*l.*, or 110*l.*, according as the return journey is completed in three, six, or twelve months. The charges on the Messageries Maritimes are about the same. The Star, Clan, and British India lines make more moderate charges, but the pace is correspondingly slower. It is little use making a journey of more than 5000 miles for a brief visit; and it may be presumed that, except where the circumstances are extraordinary, students would find it convenient to stay in Ceylon for three or four months, or more. Little is to be gained by scamping an expedition such as this, in which it may often happen that a man may gain his first and last experience of tropical nature; further, the surroundings are so new that it is some little time before one with even a good knowledge of our temperate flora can accommodate himself sufficiently to them to carry on successful work. We may then regard the cost of the journey as 100*l.*, and the time required to make it a success about six months. The choice of season is an important point: in a country of alternating wet and dry

periods it is well to experience both, and for the botanical collector it is important that collections should be finally made up in dry weather; it would be found that leaving England in November, and landing at the beginning of December, the weather would still be wet and vegetation luxuriant, but preservation of dry species would be difficult: a gradual change would be experienced, till in February and March the dry and hot season would have come in, vegetation would be more or less checked, and the preservation of dry specimens would be easy. Returning towards the end of March the English winter would be past, and, if he be a teacher, the traveller would be in time for the summer session in our Universities or medical schools.

Once on the spot the first question is one of accommodation. At Peradeniya there are neither hotels nor lodgings; a house must be taken and temporarily furnished, and it is surprising how cheaply this can be done. I took a small bungalow, the rent of which was Rs. 40 per month; friends lent me some articles of furniture, and an expenditure of Rs. 150 supplied all else that was required for temporary housekeeping. The cost of keeping house, including the wages of two native servants, rent, &c., with a margin for incidental expenses, may be set down at about Rs. 250 per month; allowing further some Rs. 200 for travelling expenses, it will be found that Rs. 1,500 will represent the total necessary expenses of residence in the island for four months. But in its present depreciated state, the rupee is worth only about *1s. 6d.*: it will therefore be sufficient to lodge about 115*l.* at a bank in Ceylon to cover all necessary expenses for four months' residence. I would not advise, however, that that exact sum only should be transferred; it would be more prudent to allow a margin for possible contingencies. The total expenses of a six months' trip to Peradeniya may thus be set down as 250*l.* But there are various ways in which strict economy might reduce the cost, while if two friends were to club together, their individual expenses for housekeeping would be considerably below the sum above stated for one. Thus it will be seen that neither in difficulty of transit nor in point of expense are there sufficient obstacles to prevent a visit to Peradeniya, or some similar station, finding a place in the programme of the career of an average botanist. One of the chief obstacles will be felt by many to be the loss of possible opportunities while absent, or the break in continuity of teaching, or other work in which a man may be already engaged. I venture to think that these are much overrated objections; and against them may be set the very great advantages which a tropical visit carries with it. A further question is, at what period in a man's career will a visit of this sort best repay him? Some will say immediately after taking his degree: but I am inclined to think that even a first-class man is at that time hardly prepared to make the best of the opportunity should it offer. The experience gained by a few years of teaching and of original work at home will indicate what is to be expected and what is to be looked for, and will fit a man in many ways for striking out new lines for himself, even if it have not already defined for him a clear line of research. On the other hand, it is important that travelling should be undertaken before a man settles in life, so that his mind may be as free as possible from distractions and anxieties.

We may now pass on to consider what are the specific advantages presented by Peradeniya as a station for botanical work. It is, as I have said, easily accessible; being more than 1500 feet above the sea, the excessive heat of the low country is avoided, and it may be regarded as a decidedly healthy place. Secondly, it is situated in a central position, both as regards the whole island, and as regards the chief lines of communication by rail and road. Thus it is easy to gain access to the low country by train to Colombo, whence roads, traversed often by horse coaches, will lead along the coast, or inland in various directions; or, taking the up-country line, Newara Eliya may be visited, which lies about 6000 feet above the sea, and would serve as a good centre for working the higher levels; or again, a journey northwards by train and coach to Anuradhapura would give an insight into the low-level vegetation of the drier northern districts. From the above notes it will be readily seen how varied is the character of the country within easy reach from Peradeniya, presenting within a comparatively small area districts varying from the sea-level to 8000 feet, and including both damp and relatively dry areas at low levels. This in itself would lead one to expect a rich and varied flora; and in fact the list of native plants now numbers some 3000 species, a very considerable proportion of which are peculiar to the island. These and other natural advantages are, however, eclipsed by the importance of the Royal Gardens themselves as providing a field for those hitherto unfamiliar with tropical nature. Here there are collected in a small area a great variety of species, both native and imported; truly no botanist who has resided at Peradeniya can any longer complain of want of scope; if he does not find ample material for future work, he can only lay the blame on his own want of imagination. In the excellent herbarium and library, as well as in the fine series of coloured figures of native plants which are lodged in the Garden, he would find the greatest assistance in recognising and naming plants collected; while lastly, in the presence of the Director, who is the best living authority on the flora of Ceylon, are found those social and scientific elements which go far to enhance the pleasure of a visit to Ceylon.

In my former article mention was made of Java, where the Gardens of Buitenzorg, presided over by Dr. Treub, present great attractions for botanists. In my case, shortness of the time at my disposal prevented a visit to this famous Garden, and probably the same difficulty will present itself to others. There is, however, one conspicuous advantage which it possesses over Peradeniya as a station for botanical research, viz. a well appointed laboratory. If, as seems not improbable, a journey to the tropics and a period of steady work among tropical plants become a usual prelude to a career of active teaching in botany, ought not the English to provide themselves with some suitable station for such work? Is every man, whether well-to-do or impecunious, to depend upon his own resources alone for laboratory accommodation, reagents, glass, and all other accessories necessary for his work? or are we to be content to send our botanists to suck what advantage they can from the hospitable Dutch, just as we send our forestry students to study with the French? Surely it would be a most legitimate way of extending the usefulness of the Garden at Peradeniya, and, in a small way it is true, of guarding the credit of England as a tropical Power, to establish a laboratory for the use of travellers. It need not be a large or conspicuous building. Dr. Trimen tells me that suitable accommodation for the present could be found in the buildings already standing in the Gardens, and probably 100*l.* would cover the initial cost of supplying the bare necessaries of life in the laboratory. The knowledge that such accommodation would be found at the other end would certainly encourage those who are doubtful to undertake a journey to Ceylon.

It may be noted that no mention has been made of the Western tropics as a field for research; there can be no doubt as to the richness of the field, but I am not aware that there are any stations in the West which can compare with Peradeniya or Buitenzorg in convenience, accessibility, and general adaptation to the requirements of those who contemplate only a comparatively short visit.

Lastly, the cost of the journey will be found to be the most frequent deterrent from undertaking it; 250*l.* is a large sum to spend upon six months' work which can bring no direct financial return, however great may be the ultimate advantage gained from it; travelling Fellowships are

few; but still there are other sources from which grants may well be made to assist really promising students in attaining so desirable an end; and it is to be hoped that it may be regarded as a legitimate and not unfrequent outlet for public or private grants, to enable young men, who will ultimately engage in teaching, towards the attainment of experience which must always be of value to them in the exercise of their profession.

F. O. BOWER

NOTES

THE following is the list of Fellows elected into the Royal Society on Friday last, June 4:—Shelford Bidwell, M.A., William Colenso, F.L.S., Harold B. Dixon, F.C.S., Major-Gen. Edward Robert Festing, R.E., Andrew Russell Forsyth, M.A., Prof. A. H. Green, M.A., Prof. Victor Horsley, F.R.C.S., Raphael Meldola, F.R.A.S., Philip H. Pye-Smith, M.D., Henry Chamberlaine Russell, B.A., Adam Sedgwick, M.A., Prof. W. Cawthorne Unwin, B.Sc., Robert Warington, F.C.S., Capt. William James Lloyd Wharton, R.N., Henry Wilde.

ARRANGEMENTS are being made by the officers of several French Societies for holding an International Congress at Biarritz for discussing papers upon climatology, mineral and thermal springs, and allied subjects. A letter has been received from the Foreign Office transmitting copies of documents, and stating that the French Government is anxious that members of scientific Societies in this country should assist. The co-operation of the Royal Meteorological Society has also been specially asked by the President of the Congress, Dr. Durand Fardel. The sittings at Biarritz will occupy the first week in October, and be followed by a three weeks' tour to the principal watering-places of Southern France. Fellows of the Royal Meteorological Society will be allowed to travel over all French railways at half price. For further particulars apply to the Assistant Secretary of the Society.

THE Council of the Society of Arts have awarded the Society's silver medals to the following readers of papers during the Session, 1885-86:—To Prof. Francis Elgar, LL.D., for his paper on the load-lines of ships; to Henry Davey, for his paper on machinery in mines; to Prof. W. C. Unwin, for his paper on the employment of autographic records in testing materials; to C. V. Boys, for his paper on calculating machines; to Prof. Leonard Waldo, D.Sc., for his paper on watch-making by machinery; to John Mackenzie, for his paper on Bechuanaland and Austral Africa; to Edward Combes, C.M.G., for his paper on the industries and commerce of New South Wales; to G. Gordon Hake, for his paper on Cyprus since the British occupation; to Prof. W. N. Hartley, F.R.S., for his paper on photography and the spectroscope in their application to chemical analysis; to Prof. R. Meldola, for his paper on the scientific development of the coal-tar colour industry; to B. H. Baden Powell, C.I.E, for his paper on Indian manufactures from a practical point of view; to Capt. Richard Carnac Temple, for his paper on the every-day life of Indian women. Thanks were voted to the following members of the Council for the papers read by them:—To Capt. Douglas Galton, D.C.L., C.B., F.R.S., for his paper on results of experiments on mechanical motors for tramways made by the Commission at the Antwerp Exhibition; to W. H. Preece, F.R.S., for his paper on domestic electric lighting.

THE Society of Arts *conversazione* will be held, by permission of the Royal Commission, at the Colonial and Indian Exhibition, South Kensington, on Friday, July 16 next.

MR. TALFOURD ELY has resigned the Secretaryship of University College, London.

THE Russian Geographical Society has awarded this year its great gold medal to M. Yurgens for his remarkable work as chief of the Arctic Meteorological Station at the mouth of the Lena. The Medal of Count Lütke has been awarded to Col. Pyevtsoff for his most valuable account, full of new and interesting information, of his journey in N.W. Mongolia and Northern China, published, with a map, in the fifth volume of the West Siberian Branch of the Society. Great gold medals have been awarded to M. Dmitrevsky for his annotated translation of Otano Kitoro's work on Corea, and M. Tereshkevitch for his statistical description of the Government of Poltava. Small gold medals were awarded, to Prof. Lenz for his work in the capacity of President of the Physical Geography Section of the Society; to M. Fuss, for his calculations of the great levelling through Siberia; to the Director of the Tiflis Observatory, M. Milberg, for his magnetical observations carried on in connection with those of the Polar stations; and to M. Mainoff, for his work on the customary law of the Mordovians. Several silver medals were distributed to MM. Gedeonoff, Fedoroff, Krasnoff, and Ignatieff for astronomical, geological, and botanical works; to several persons who have sent observations on thunderstorms and rains, as also for various ethnographical and statistical researches.

THE Town Council of Banff, along with the Council of the Banffshire Field Club and Office-Bearers of the Banff Literary Society, have formed themselves into a General Committee (with power to add to their number) to promote the subscription of a fund for the erection of a memorial in Banff to the memory of the late Mr. Thomas Edward, A.L.S., "The Scottish Naturalist." The Committee feel sure it will be the desire of many throughout the whole nation to contribute to this fund, and to combine to make the memorial worthy of the universal admiration and respect entertained for Mr. Edward. In order to afford full opportunity for this, it is proposed to add to the Committee ladies and gentlemen throughout the various parts of the country who so appreciate Mr. Edward's life and work as to be willing to interest themselves in providing some substantial and suitable perpetuation of his memory. Communications should be addressed to the Interim Secretary, Mr. John Allan, Town Clerk of Banff.

THE Prince of Wales, considering that the rates of admission to the Colonial and Indian Exhibition at South Kensington should be brought within the means of all classes residing in the Metropolitan area, is making arrangements with the Railway Companies and other bodies in a position to co-operate in the organisation of a scheme whereby every working man, woman, and child will have an opportunity of visiting the Exhibition at greatly reduced prices on every week-day except Wednesday from the middle of August until the close of the Exhibition. Arrangements for enabling the working classes of the provinces to visit the Exhibition have been for some time in operation, under his Royal Highness's direction.

THE first of the conferences convened by the Geologists' Association on "The Mineral Resources of the Colonies and India," was held at the Colonial and Indian Exhibition on Saturday afternoon (June 5), when a lecture was delivered by Prof. V. Ball, F.R.S., on "The Mineral Resources of India and Burmah." The discussion brought out the urgent need for reform of the mining laws of India, and the following resolution, proposed by the chairman (Sir R. Temple), seconded by the Duke of Manchester, and supported by the lecturer and others, was unanimously adopted:—"This Conference having had under its review the mineral resources of India and the obstacles to development and exploitation of the same through the want of suitable or sufficient mining laws, respectfully urges upon the Secretary of State for India the desirability of regulating or revising the regulations for the working of mines in British India, including Burmah, and for the protection of mining interests

therein, and also of negotiating arrangements to the same effect with the Native States." The next conference will be held on Saturday, June 19, when Prof. T. Rupert Jones, F.R.S., will lecture on "The Mineral Resources of South Africa." Sir Charles Mills will preside.

THE latest news from Catania reports that the eruption of Mount Etna has almost entirely ceased. The lava-streams, stopping within 300 metres of Nicolosi, have become hard enough to walk on, but repeated shocks of earthquake of considerable violence continue throughout the region. A huge gulf has yawned at Acireale, but no disasters are reported. A correspondent of the *Standard* writing from Catania on May 27 sends some valuable notes. "The stream of lava issuing from Monte Penitello (an eminence about 4980 feet high, and about 7 kilometres distant from Nicolosi) has travelled a longitudinal course of about 6 kilometres, and has formed four basins, the last of which is behind Monte Nocella. The width of the stream is about 2½ kilometres. The stream flows directly southward from the north-east. The western branch, which flows towards Dogola Arcino, has done but little damage, traversing in its course mostly gravelly soil. Prof. d'Amico, who is studying the phases of the eruption from the Observatory of Pennesi, in Acireale, has contributed to the archives of Catania a complete record of all the volcanic disturbances which he has noted up to date. The maximum number of 92 telluric convulsions was registered on the 19th inst. On the following day there were only 20, but subsequently the number rose from 25 to 30, 27, 35, and finally to 52, on Tuesday the 25th."

SEVERAL shocks of earthquake were felt at Smyrna, in the Island of Chios, and in the Erythrian Peninsula on the night of June 5.

PROF. MILNE recently made an attempt to sound the depth of the crater of Asamayama, the active volcano about seventy miles to the north-west of Tokio, and in the historic period one of the most destructive of all Japanese volcanoes. The attempt however failed owing to unfavourable weather. No details of the experiment or of the precise manner in which it was to be carried out have been received as yet.

WE have already referred to the threatened abolition, of alteration, of the Imperial College of Engineering in Tokio, in consequence of administrative changes which have resulted in the abolition of the Department of Public Works, under which the College was placed. As the names of several men well known in the English scientific world have been associated with this institution, we are glad to be able to say that the change has not been so great as was at first apprehended. Mr. Mori, the new Minister of Education, long the representative of Japan in this country, has established a new University, to which the Engineering College has become affiliated, as well as the former Medical College. Except in two important details, the organisation remains the same. The College now comes under the exclusive control of Japanese, in other words, the post of Principal, hitherto held by Dr. Divers and his predecessor, is no longer to be occupied by a foreigner, and the whole University is to be governed by its professors, and not by ordinary officials. The idea, says the *Japan Mail*, is "to emancipate learning and its professors from the too often ignorant and always hampering control of the ordinary official." Everything now is subject to the professorial body. Japan is not to lose the services of any of the foreign professors of the College. Dr. Divers continues as Professor of Chemistry, but in the Science instead of the Engineering College. Prof. Milne continues in the Chair of Mining Engineering, and there is a probability that he will also be invited to occupy a Chair of Seismology which it is proposed to found. It thus appear that the change is not one which interferes with the work of the College; if anything its status as an educational institution is increased, because it now forms an integral portion of the highest teaching establishment in the country. It is not clear from the account from which we quote whether the College will remain in the fine buildings which were specially erected for it, or whether it will be removed to the University, which is some distance away.

IN connection with this change, the professors and students of the College, meeting for the last time as members of the Engineering College, presented the Principal, Dr. Divers, with a handsome bronze vase, inlaid with gold. Prof. Milne, as the senior, in handing the present to Dr. Divers on behalf of the subscribers, made a short speech referring to the services of the Principal to Japan, his pupils, and colleagues; and with this ceremony an institution in which English science has, or should have, a peculiar interest, came to an end, but only to rise again in another shape, let us hope for increased usefulness to Japan.

THE Chair of Seismology which has been founded in the Science College of the new University of Japan has been filled by the appointment of Mr. K. Sekiya as professor.

AT Cambridge to-day (Thursday) a vote of the Senate is to be taken in favour of appointing a syndicate to obtain plans and estimates for the erection of a Geological Museum, to confer with the Sedgwick Memorial Committee, and to report before the middle of the Michaelmas term. Thus it appears likely that at last the Sedgwick Museum will become an actual fact, after twelve years of incubation.

THE current number of the *Proceedings* of the Bath Natural History and Antiquarian Field Club contains several papers of scientific interest. Mr. Broome continues his list of fungi found in the neighbourhood of Bath. Mr. Blomefield, writing on the firs of Bournemouth, argues that these trees are true natives of that part of the country, in opposition to the theory that the Scotch fir, though indigenous in Scotland, is not indigenous in England. Dr. Norman describes the fresh-water algæ of the Bath thermal waters; and Mr. McMurtrie the salt-springs found at great depths in the Coal-measures at Radstock.

FUNGI also occupy a considerable space in the *Proceedings* of the Belfast Naturalists' Field Club, as in those of the Bath Society, for Mr. Lett gives a list of the fungi of the North of Ireland which fills more than 50 pages. Dr. Malcolmson describes some recent *Ostracoda* of Belfast Lough, and appends an elaborate table of their distribution. Mr. Joseph Wright adds two lists—one of the Foraminifera of Down and Antrim, the other of the Cretaceous Foraminifera of Keady Hill in the county of Derry. The record of the meetings is very full, and contains much information on various scientific subjects connected with the North of Ireland.

ARRANGEMENTS have been made by the Colonial and Indian Aquarium authorities to bring over a consignment of some of the principal species of fish in the waters of Java for purposes of exhibition. The British India Steamship Company have undertaken to transmit them in specially made glass carriers, which have been forwarded to Java for that purpose. Fourteen specimens of the *Chelone midas*, or green turtle, have lately arrived at the Aquarium from West India; also a collection of land crabs from the same quarter.

THROUGH the instrumentality of the National Fish-Culture Association the River Lea was last week enriched with a quantity of salmon fry, which were turned into those *locales* most suitable to their requirements Although the Lea is in a very polluted condition, there are portions free from contamination where fish thrive well. The Severn Fishery Board have turned into their river a large number of salmon fry. The ova from

which they were hatched out were collected in the first instance by the Board and forwarded to the National Fish-Culture Association to incubate, which was done most successfully. The Severn Fishery Board are to be commended upon the action they have taken to replenish their river with fish, as they set an example to other bodies having the interests of their waters at heart. The hatchery at South Kensington and Delaford belonging to the Association might become an extensive medium in carrying such an object into effect at a minimum cost.

THE additions to the Zoological Society's Gardens during the past week include a Nisnas Monkey (*Cercopithecus pyrrhonotus*) from Nubia, presented by the Rev. W. MacGregor; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. J. Coston; a Common Badger (*Meles taxus*), British, presented by Mr. C. A. Ross; six Black-footed Penguins (*Spheniscus demersus*) from South Africa, presented by Capt. John Hewat; four Siamese Blue Pies (*Urocissa magnirostris*) from Siam, two Small Hill-Mynahs (*Gracula religiosa*) from Southern India, a Rufous necked Weaver Bird (*Hyphantornis textor*) from South Africa, presented by Mr. J. M. Cook, F.Z.S.; a Golden Eagle (*Aquila chrysaetos*) from Russia, presented by Mr. Walter Holdsworth; six Long eared Owls (*Asio otus*), British, presented by Mr. G. B. Burnand; a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, three Ruffs (*Machetes pugnax*), British, deposited; a Glaucous Macaw (*Ara glauca*) from Paraguay, four Crested Pigeons (*Ocyphaps lophotes*) from Australia, four Amherst's Pheasants (*Thaumalea amherstiæ*) from China, two Great American Egrets (*Ardea egretta*) from South America, two Lapwings (*Vanellus vulgaris*), British, four Indian Tree Ducks (*Dendrocygna arcuata*) from India, purchased; a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

COMET BROOKS II.—The following ephemeris for this comet is by Prof. C. Frisby (Science Observer Special Circular, No. 67):—

For Greenwich Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log r	Log Δ	Brightness
June 11	6 23 20	69 15·0 N.	0·0380	0·1783	0·26
15	6 58 55	66 54·1	0·0557	0·2015	0·21
19	7 27 41	64 28·3	0·0734	0·2275	0·17
23	7 39 51	62 58·9	0·0909	0·2486	0·14
27	7 59 57	60 49·5 N.	0·1081	0·2704	0·12

The brightness on May 2 is taken as unity.

COMET BROOKS III.—Dr. S. Oppenheim has calculated the following elements and ephemeris for this comet from observations made on May 25, 28, and 30, at Arcetri, Rome, and Vienna:—

$$T = 1886 \text{ June } 2{\cdot}90285 \text{ Berlin M.T.}$$

$$\left.\begin{array}{l} \omega = 173^\circ\ 57'\ 49''{\cdot}6 \\ \Omega = \ \ 47\ \ 14\ \ 43{\cdot}5 \\ i = \ \ 16\ \ \ 8\ \ 52{\cdot}3 \end{array}\right\} \text{Mean Eq. } 1886{\cdot}0.$$

$$\log q = 0{\cdot}170230$$

Ephemeris for Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log r	Log Δ	Brightness
June 8	12 18 3	1 1·8 S.	0·1709	9·9183	0·87
12	12 26 1	3 32·8	0·1721	9·9274	0·83
16	12 34 25	6 1·6	0·1739	9·9375	0·79
20	12 43 15	8 27·4	0·1763	9·9486	0·75
24	12 52 27	10 49·2	0·1793	9·9605	0·70
28	13 1 59	13 6·1 S.	0·1828	9·9732	0·65

The brightness on May 25 is taken as unity.

The comet is faint, and not bright as stated in the telegram announcing the discovery.

SPECTROSCOPIC DETERMINATION OF THE MOTION OF THE SOLAR SYSTEM IN SPACE.—Dr. R. von Kövesligethy mentions (*Astronomische Nachrichten*, No. 2731) that some three years ago he tried to deduce the speed with which the sun is travelling in space and the point to which its progress is directed, from the observations of the displacements of lines in stellar spectra published in the *Monthly Notices*. The latter inquiry he gave up, as the data supplied did not seem sufficiently trustworthy for a satisfactory result to be obtained from them. He therefore assumed the apex as found from the discussion of the proper motions of stars, viz. R.A. = 216°·0, Decl. = 35°·1 N. Taking the simple arithmetical mean of the observations of the individual stars observed—about 70 in number—he found the speed of translation of the solar system to be about 8·6 geographical miles per second. This rate of motion would agree far better with Struve's value, derived from the consideration of the proper motions of stars, than Herr Homann's (NATURE, vol. xxxiii. p. 450) result does. Dr. Kövesligethy does not, however, place much reliance on the result he has thus obtained.

PUBLICATION OF THE ZONE-OBSERVATIONS OF THE "ASTRONOMISCHE GESELLSCHAFT."—M. Doubiago, who has succeeded the late Marian Kowalski as Director of the Kasan Observatory, has recently issued a volume containing the observations made at Kasan during the years 1869 77, of the stars situated in the zone between 75° and 80° of north declination. The principal object of this work, undertaken by M. Kowalski by arrangement with the *Astronomische Gesellschaft*, was the determination of the positions of the stars contained in this zone down to the ninth magnitude. M. Kowalski, however, determined to include in his work all the stars of the *Bonner Durchmusterung* situated in the above-mentioned zone, about 5000 in number, as well as a considerable number of fainter stars. The observations, commenced in 1869, were finished in 1879, and the present volume contains 14,329 observations, that is, about half the total number necessary to complete the projected scheme of having four observations of each star. The results are given in the usual form in which zone-observations are published, viz. the apparent positions for each day of observation are given, together with the reduction to the mean place for the beginning of the year. As far as we remember, Kasan has the honour of being the second of the observatories engaged on the zone work of the *Astronomische Gesellschaft* which has published their observations, Prof. Krüger having already published his Helsingfors zones (55° to 65° of north declination) in two volumes, the first volume having appeared in 1883, and the second in 1885.

THE MADRAS OBSERVATORY.—Mr. Pogson's report for the year 1884 has recently been issued. He points out that during the year a work on "Telegraphic Longitude Determinations in India" was printed and published. The number of observations made with the meridian circle during the year was 844, which brings up the total number of observations made with this instrument since 1862, now awaiting publication, to 51,722. The separate results and annual catalogues will fill eight volumes, to be followed by a final catalogue of about 5000 stars, reduced to the epoch 1875. All the reductions are completed up to date, and Mr. Pogson hopes that these volumes will appear in fairly rapid succession. We hope so too. The speedy publication of a catalogue of 5000 stars would do much towards restoring the Madras Observatory to the position, as a scientific institution, which it formerly held.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 JUNE 13-19

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 13

Sun rises, 3h. 45m.; souths, 11h. 59m. 45·2s.; sets, 20h. 15m.; decl. on meridian, 23° 14′ N.: Sidereal Time at Sunset, 13h. 43m.

Moon (Full on June 16) rises, 16h. 50m.; souths, 21h. 51m.; sets, 2h. 44m.*; decl. on meridian, 13° 26′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	3 43	12 7	20 31	24 26 N.
Venus	2 0	9 10	16 20	12 52 N.
Mars	11 36	18 1	0 26*	4 7 N.
Jupiter	12 5	18 22	0 39*	2 32 N.
Saturn	5 2	13 13	21 24	22 41 N.

* Indicates that the setting is that of the following morning.

M signifies maximum ; *m* minimum.

BIOLOGICAL NOTES

DEVELOPMENT OF OPHIOPHOLIS AND ECHINARACHNIUS.—In the last series of studies from the Newport Marine Zoological Laboratory we find a memoir by Mr. Walter Fewkes, on the development of an Ophiuroid (*Ophiopholis aculeata*, Gray) and of an Elypeastroid (*Echinarachnius parma*, Gray). But few observations have been published on the metamorphosis of Ophiopholis, and these often misleading. The eggs would appear to be extruded separately into the water, and the young pass through a metamorphosis in which a pluteus-larva is formed ; the development of this pluteus is different from that of any described Ophiuran, though allied to that in Ophiothrix. The ova were voluntarily shed by the female on August 17 ; they were fertilised outside the body, and appeared to be very hardy. The yolk has a central and a peripheral region, which are distinguishable in the eight-cell and previous stages of segmentation. The cleavage is like that of other Echinoderms. A gastrula is formed by the invagination of the blastoderm, and consequently the stomach of the pluteus is an infolded wall of the blastoderm, and not formed by delamination from the cells in the cavity. The mesoderm-cells originate in two lateral clusters. The oldest pluteus observed was a little more than three days old ; they, however, appeared to be easily raised, and it is to be hoped that they will be yet traced to an adult form. In Echinarachnius the sexes are distinct, and in some cases there were colour distinctions. In the experiments on the ovum of *E. parma*, artificial fertilisation was resorted to from the middle of July to the end of August ; it was easily effected. In its mode of segmentation it resembles that of other Echinoderms. It has no polar globules, but possibly these may be formed while the egg is in the ovary. As in some other Echinoderms, a gastrula is formed by invagination. The pluteus figured by A. Agassiz in the revision of the Echini as probably that of Echinarachnius proves to belong to this species at about a week old. The development of the young Echinarachnius on the water-tube of the pluteus resembles that of other sea-urchins. The rosette-form of the water-tubes described in other Echinoderms also occurs. The first-formed calcareous deposits of the test are trifid in form, and vary in number in different specimens. The extremity of each trifid division bifurcates later in its growth, and the calcareous body thus formed appears to be inclosed in a transparent wall, which has a spherical outline. Spines are very early formed, and are proportionately very large as compared with those of the adult. The various stages are illustrated in numerous figures on eight, in several cases folding, plates.—*Bull. Mus. Comp. Anat. Harvard College*, vol. xii. No. 4, March 1886.

THE LEECHES OF JAPAN.—In the April number of the *Quarterly Journal of Microscopical Science*, Dr. C. O. Whitman publishes the first hundred pages of a memoir on the leeches of Japan. The material for the study was collected while the author was connected with the University of Tokio (1879–81). The coloured drawings accompanying the memoir were executed by Mr. Nomura, a young Japanese artist, and they well deserve the remarks of the author: "Mr. Nomura's attention to the minutest details, his infinite patience, trained eye, and his remarkably skilful brush, have given results that are marvels for neatness and accuracy." The first part of this study treats of the land leech (*Hæmadipsa japonica*), the medicinal leech (*Hirudo medicinalis*), and of three species of toothless leeches, which form a new genus, Leptostoma. It also contains a comparison of a few species from Europe, Asia, and America, and a considerable portion is devoted to a comparative study of the different genera, in the endeavour to find a satisfactory basis of classification. This has in a great measure been found in a law of abbreviation of the somites, which, in addition, gives a key to the phylogeny of the genera. The land leech is shown to be a highly instructive and specialised form. The genus Hirudo has been re diagnosed (p. 364), and while internal structure has been dealt with to only a very limited extent, still some interesting facts in connection with the nephridial organs of the land leech are detailed, and the existence of from twelve to fourteen sense-organs on the first ring of each complete somite is demonstrated, and they are homologued with the eyes, having possibly also other sense-functions. The author reserves the genus Hæmadipsa for the land leeches of Ceylon, India, and Japan, with three jaws and five inter-genitalia rings. He ascribes the genus to Tennant, but may it not have been formed by Baird? *H. japonica* is confined to the mountain slopes and ravines, never descending into the plains. It is not only a mountain leech, but it keeps habitually to the ground, living in moss, or under damp leaves and rubbish. They are most voracious, and on the approach of man or beast are at once on the alert. They advance by rapid strides. They bite so gently as scarcely to attract attention, but the wound is deep, and the scar is more or less permanent. They gorge on for about 30 to 40 minutes, and then drop ; while sucking they become bedewed with a transparent liquid, which keeps them moist. If placed in water, they do not swim but sink, and then creep out ; and while having a decided preference for a terrestrial life, can support life for days in water. If into a jar of hungry leeches a puff of breath is blown, they become immensely excited, and it will be difficult to keep them in ; while trying to keep back one, a dozen others will rush out. In a most interesting series of paragraphs Dr. Whitman traces the intimate relation that exists between these land and the medicinal leeches, the latter essentially fresh-water forms. The geographical area of land-leeches is mainly within the tropics, though in Japan they are exposed to a wide range of temperature. *H. nipponia* is described as a new Japanese medicinal leech, well known to the Japanese, and with habits and mode of life just like our European leech. Leptostoma, a new genus, is established (p. 376) on three species of almost edentulous leeches, which, though having a common ancestry with Hirudo, were not derived from it. All three species, *L. acranulatum*, *L. edentulum*, and *L. pigrum*, are from Tokio, and are fully diagnosed and beautifully figured. The segmental organs are shown to be sense-organs, and that from them the eyes have developed, so that they may be regarded as incipient eye spots.

NEW ELEMENT OF THE BLOOD AND ITS RELATION TO COAGULATION.—In an important paper by Mr. Geo. T. Kemp on this subject, he comes to the conclusion that in addition to the red corpuscles and leucocytes the blood normally contains a third histological element—the "plaques." These have been variously considered as young red corpuscles ; as nuclei floating in the blood ; as being derived from the red or the white corpuscles ; as being fibrin ; and as being globular depositions produced by cooling of the blood ; but the author proves that, although strong resemblances exist between the plaques and other histological elements of the blood, there is not yet sufficient evidence to establish a *genetic* connection. The plaques should therefore, at least for the present, be regarded as independent elements. When the blood is drawn, the plaques break down almost immediately, and this is not true of any other element of the blood. This breaking down of the plaques seems intimately connected, in its time relations at least, with the clotting of the blood. If a good-sized drop of blood from a finger be let fall on a cover-glass, and as quickly as possible washed by a good jet of ·75 per cent. NaCl solution, and then examined under the

microscope, the plaques, which have a property of sticking to the glass slip, will be found to fill the field; some will be isolated, some will be in groups; they will now appear glistening and granular, and their contours are jagged, becoming more and more so as time elapses; finally only a granular mass will be found. If, however, a drop of osmic acid be placed on the finger before the drop of blood be drawn, all the elements will be found presenting their normal appearances, and the plaques will be seen as pale homogeneous structures varying greatly in size, but for the most part about one-third or one-fourth of the diameter of the red corpuscles; they are biconcave, but not as much so as the red corpuscles. Once thus hardened they never change their form, but the plaques first referred to will be found to alter their form very speedily, and *pari passu* with these changes, processes are seen which run out from the granular masses, and when coagulation sets in these processes are nearly always found to be continuous with threads of fibrin. The connection between the breaking down of the blood is not histological but chemical. The plaques appear to give up a soluble substance which is active in coagulation. This active agent is most probably a *fibrin* ferment. Fibrin is deposited histologically independent of any of the cellular elements of the blood, and when the clot is very scant. The fibrin is seen deposited as long, needle-shaped, crystal-like bodies. — *Studies from Biolog. Lab., Johns Hopkins Univ.*, vol. iii. No. 6, May 1886.

ON RECENT PROGRESS IN THE COAL-TAR INDUSTRY[1]

II.

AZO-COLOURS.—Amongst the most important of the artificial colouring matters may be classed the so-called azo-colours. These colours are chiefly bright scarlets, oranges, reds, and yellows, with a few blues and violets. They owe their existence to the discovery by Griess, in 1860, of the fact that the so-called azo-group – N = N – can replace hydrogen in phenols and amido-compounds. But it is to Dr. O. N. Witt that is due the honour of having given the first start in a practical direction to the chrysoidine class of azo-colours by the discovery of chrysoidine, and perhaps still more so by the suggestions contained in a paper read before the Chemical Society. Dr. Caro, of Mannheim, was also acquainted with several compounds which belong to this class at the time Witt published his results, but it does not appear that he made practical use of them until Witt introduced the chrysoidines and tropeolines. To Roussin, of the firm of Poirrier of Paris, is due the credit of having first brought into the market some of the beautiful azo-derivatives of naphthol. Griess, therefore, as the original discoverer of the typical compounds and reactions by which the azo-colours are obtained, may be considered as the grandfather, whilst Roussin and Witt are really the fathers, of the azo-colour industry. Nor must it be forgotten that it is to Perkin we owe the recognition of the value of the sulpho group in relation to azo-colours, a discovery patented in 1863. Moreover it is interesting to note that changes in colour from yellow to red and claret are effected by the increase in the molecular weights of the radicals introduced as well as by the relative positions occupied by these groups.

Indophenol.—Witt is also the discover of a new blue dye-stuff termed indophenol, which has been used as a substitute for indigo. Certain difficulties, however, have arisen in the adoption of this colour on the large scale. The most important use indophenol is at present put to is for producing dark blues on reds dyed with azo-colours, both on wool and cotton. The piece goods are dyed a uniform red first, and then printed with indophenol white; for like indigo itself indophenol yields a colourless body on reduction, and this being a very powerful reducing agent destroys the azo-colour, being itself transformed into indophenol blue. The process works with surprising nicety and is very cheap. The blue is formed and the red discharged with such precision that patterns can be produced in which the blue discharge covers a great deal more space than the original red. This new printing process was devised by Mr. H. Koechlin, of Lorrach. The reds used for the purpose are in the case of wool the usual azo-scarlets, for cotton Congo red.

Artificial Indigo.—About five years ago the speaker had the honour of bringing before this audience[1] the remarkable discovery made by Baeyer of the artificial production from coal-tar products of indigo blue. Since that time but little progress has been made in this manufacture, as the cost of the process, unlike the case of alizarin, has as yet proved too serious to enable the artificial to compete successfully in the market with the natural indigo.

Through the kindness of a number of eminent colour manufacturers in this country and on the Continent, the speaker was enabled to illustrate his subject by a most complete series of specimens both of the colours themselves and of their application to the dyeing and printing of fabrics of all kinds. His thanks are especially due to his friend, Mr. Ivan Levinstein, of Manchester, for the interesting series of samples of cloth dyed with known quantities of fifty different coal-tar colours, each having a different chemical composition; also to the same gentleman, and to Messrs. Burt, Boulton, and Haywood, of London, for the interesting and unique series of specimens indicating the absolute quantities of products obtainable from *one ton of coal*, as well as for much assistance on the part of Mr. Levinstein in the preparation of the experimental illustrations for this discourse. To Dr. Martius of Berlin for a valuable series of colours, especially the well-known Congo red, made by his firm, including samples of wool dyed therewith, he is also much indebted. For the interesting details concerning indophenol and its applications the speaker owes his thanks to Dr. Witt and M. Koechlin.

Coal-tar Antipyretic Medicines.—Next in importance to the colour industry comes the still more novel discovery of the synthetical production of antipyretic medicines.

Up to this time quinine has held undisputed sway as a febrifuge and antiperiodic, but the artificial production of this substance has as yet eluded the grasp of the chemist. Three coal-tar products have, however, been recently prepared which have been found to possess strong febrifuge qualities, which if still in some respects inferior to the natural alkaloids, yet possess most valuable qualities, and are now manufactured in Germany at Höchst and at Ludwigshafen in large quantity. And here it is well to call to mind that the first tar colouring-matter discovered by Perkin (mauve) was obtained in 1856 during the prosecution of a research which had for its object the artificial production of quinine.

In considering the historical development of this portion of his subject, the speaker added that it is interesting to remember that the initiative in the production of artificial febrifuges was given by Prof. Dewar's discovery in 1881 that quinoline, the basis of these antipyretic medicines, is an aromatic compound, as from it he obtained aniline. Moreover that Dewar and McKendrick were the first to observe that certain pyridine salts act as febrifuges. So that these gentlemen may be said to be the fathers of the antipyretic medicines, as Witt and Roussin are of the azo-colour industry.

Kairine, the first of these, was discovered by Prof. O. Fischer, of Munich, in the year 1881, whilst engaged on his investigations of the oxyquinolines. The febrifuge properties of this substance were first noticed by Prof. Filehne, of Erlangen. Kairine is manufactured from quinoline, a basic product derived from aniline by heating it with glycerin and nitrobenzene by the following process. When treated with sulphuric acid, SO_4H_2, it forms quinoline sulphonic acid, and this when fused with caustic soda yields *oxyquinoline*, which is then reduced by tin and hydrochloric acid into tetrahydroxyquinoline, and this again on treatment with C_2H_5Br yields ethyl-tetraoxyquinoline or kairine. The lowering of the temperature of the body by this compound is most remarkable, though, unfortunately, the action is of much shorter duration than that effected by quinine itself; but on the other hand, with the exception of its burning taste, it exerts no evil effects such as are often observed after administration of large doses of quinine. The commercial article is the hydrochloride, the price is 85*s.* per lb., and the quantity manufactured has lately diminished owing to the discovery of the second artificial febrifuge, antipyrine.

The following graphical formula shows the constitution of kairine:—

$$C_6H_3(OH)\begin{array}{l}\diagup CH_2CH_2 \\ \diagdown N(CH_3)CH_2 \\ \quad\;\diagup\;\diagdown \\ \quad H \quad Cl\end{array}$$

[1] A Discourse by Prof. Sir Henry E. Roscoe, M.P., LL.D., F.R.S., delivered at the Royal Institution, Friday, April 16, 1886. Continued from p. 114.

[1] "On Indigo and its Artificial Production," *Proc. Roy. Inst.*, May 27, 1881.

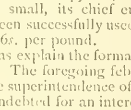
Antipyrine, the second of these febrifuges, was discovered in 1883 by Dr. L. Knorr in Erlangen, and its physiological properties were investigated by Prof. Filehne, of Erlangen. The materials used in the manufacture of antipyrine are aniline and aceto acetic ether. The aniline is first converted into phenylhydrazine, a body discovered by Emil Fischer in 1876. This body combines directly with aceto-acetic ether, with separation of water and alcohol, to form a body called pyrazol ($C_{10}H_{10}N_2O$). The methyl derivative of pyrazol derived by treating it with iodide of methyl, is *antipyrine*, its composition being $C_{11}H_{12}N_2O$. As a febrifuge, antipyrine is superior in many respects to kairine and even to quinine itself. It equals kairine in the certainty of its action, whilst in its duration it resembles quinine. It is almost tasteless and odourless, is easily soluble in cold water, and takes the form of a white crystalline powder. Its use as a medicine is accompanied by no drawbacks. It occurs in commerce in the free state. The production of antipyrine, in spite of these valuable qualities, is as yet small, its chief employment being in Germany, where it has been successfully used in cases of typhoid epidemic. The price is 6*s*. per pound.

The following equations explain the formation and constitution of this interesting body. The foregoing febrifuges are manufactured at Hochst under the superintendence of Dr. Pauli, to whose kindness the speaker is indebted for an interesting series of specimens illustrative of the manufacture of antipyrine.

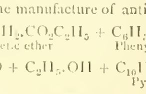
$$\underset{\text{Aceto-acetic ether}}{CH_3.CO.CH_2.CO_2C_2H_5} + \underset{\text{Phenylhydrazine}}{C_6H_5.NH.NH_2}$$
$$= H_2O + C_2H_5.OH + \underset{\text{Pyrazol}}{C_{10}H_{10}N_2O}$$

$$C_{10}H_{10}N_2O + ICH_3 = \underset{\text{Antipyrine-hydriodide}}{HI.C_{10}H_9(CH_3)N_2O.}$$

Dr. Knorr formulates pyrazol thus:



And antipyrine is



The antipyretic effect of this compound is strikingly shown in the following temperature readings in a case of typhoid kindly communicated to the speaker by his friend Dr. Dreschfeld of Manchester. Each of the second set of readings was made two hours after a dose of 30 grains of antipyrine had been administered.

I.	II.	Diff.
°	°	°
105·0	103·0	2·0
103·5	100·2	3·2
103·8	100·8	3·0
105·2	101·4	3·8
104·4	100·6	3·8

Thalline.—The third of the artificial febrifuges is *thalline*, which is offered as the tartrate and sulphate. It is manufactured by the Badische Company. Thalline is said to be used as an antidote for yellow fever. Its scientific name is tetrahydroparaquinanisol, and it was first prepared by Skraup by the action of methyl iodide and potash on paroxyquinoline.

We must, however, bear in mind that none of these synthetical febrifuges are antiperiodics, and therefore cannot be employed instead of the natural alkaloid quinine in cases of ague or intermittent fevers.

Coal-tar Aromatic Perfumes.—A third group of no less interest comprises the artificial aromatic essences, and of these may here be mentioned, in the first place, *cumarin*, $C_9H_6O_2$, the crystalline solid found in the sweet woodruff, in Tonka bean, and in certain sweet-scented grasses. This is now artificially prepared by acting upon sodium salicyl aldehyde with acetic anhydride by the reaction which is associated with the name of Dr. Perkin, and is used in the manufacture of the perfume known as "extract of new-mown hay."

A second interesting case of a production of a naturally occurring flavour is the artificial production of *vanillin*, the crystalline principle of vanilla. Vanilla is the stalk of the *Vanilla planifolia*, which incloses in its tissues prisms of crystalline vanillin, to which substance it owes its fragrance. Tiemann and Harrmann showed that vanillin is the aldehyde of methyl protocatechuic acid—

$$C_6H_3(OH)(OCH_3)CHO, [CHO : OCH_3 : OH = 1 : 3 : 4].$$

The chief seats of the vanilla productions are on the slopes of the Cordilleras north-west of Vera Cruz in Mexico, also the island of Réunion, and in the Mauritius. Since the discovery of the artificial production of vanillin, the growth of the vanilla has been very much restricted.

A variety of vanilla, termed vanillon, obtained in the East Indies, has long been used in perfumery for preparing "essence of heliotrope." This contains vanillin together with an oil, which is probably oil of bitter almonds. The essence of white heliotrope is now entirely prepared by synthetical operations. It is manufactured by adding a small quantity of artificial oil of bitter almonds to a solution of artificial vanillin; when these substances are allowed to remain for some time in contact, the mixture assumes an odour closely resembling that of natural heliotrope. Through the kindness of Mr. Rimmel the speaker was able to render the fragrance of this coal-tar perfume perceptible to his audience. Nor must we forget to mention the so-called essence of mirbane (nitrobenzene), of which about 150 tons per annum are used for perfuming soap; and artificial oil of bitter almonds, employed as a flavour in place of the natural oil.

Coal-tar Saccharine.—Of all the marvellous products of the coal-tar industry, the most remarkable is perhaps the production of a sweet principle surpassing sugar in its sweetness *two hundred and twenty* times. This substance is not a sugar, it contains carbon, hydrogen, sulphur, oxygen, and nitrogen. Its formula is

$$C_6H_4{<}\begin{matrix}CO\\SO_2\end{matrix}{>}NH,$$

and its chemical name is benzoyl sulphonic imide, or for common use, saccharine. It does not act as a nutriment, but is non-poisonous, and passes out of the body unchanged. The following is a concise statement of its properties, and mode of production from the toluene of coal-tar. It should, however, be first mentioned that the compound benzoyl sulphonic imide (saccharine) was first discovered by Constantin Fahlberg and Remsen, in America. But no patent was taken out for a commercial process till recently, and it is now patented in this country.

STEP I.—Toluene is treated with fuming sulphuric acid in the cold, or it is heated with ordinary sulphuric acid of 168½° Twaddell on the water bath, or not above 100° C. The latter method is the better. The acid is best caused to act upon the toluene in closed vessels rotating on horizontal axles.

$$\underset{\text{Toluene}}{C_6H_5CH_3} + SO_4H_2 = \underset{\substack{\text{Toluene sulphonic acids}\\\text{(ortho and para).}}}{C_6H_4\left\{\begin{matrix}CH_3\\SO_2.OH\end{matrix}\right.} + H_2O.$$

STEP II.—After all toluene (which as toluene is insoluble in the acid) has disappeared, the contents of the agitating vessel are run into wooden tanks in part filled with cold water, and the whole liquid is stirred up with chalk to neutralise the excess of sulphuric acid used and to obtain the two isomeric toluene sulphonic acids as calcium salts.

$$2\underset{\substack{\text{Toluene, ortho- and}\\\text{para-sulphonic acids}}}{\left(C_6H_4\left\{\begin{matrix}CH_3\\SO_2.OH\end{matrix}\right.\right)} + SO_4H_2 + 2(CaCO_3) =$$

$$\underset{\substack{\text{Calcium toluene ortho-}\\\text{and para-sulphonates}}}{\left(C_6H_4\left\{\begin{matrix}CH_3\\SO_3\end{matrix}\right.\right)_2Ca} + CaSO_4 + 2CO_2 + 2H_2O.$$

The neutralised mass is filtered through a filter-press to separate therefrom the precipitate of gypsum, which is washed with hot water, and the washings added to the filtrate.

STEP III.—The calcium salts are now treated with carbonate of sodium, to obtain the sodium salts, with precipitation of carbonate of calcium. The precipitate is removed by means of a

filter-press from the solution containing the sodium ortho- and parasulphonates.

$$\left(C_6H_4\begin{cases}CH_3\\SO_3\end{cases}\right)_2Ca + Na_2CO_3 = CaCO_3 + 2C_6H_4\begin{cases}CH_3\\SO_3ONa.\end{cases}$$

The sodium toluene sulphonates

STEP IV.—The solution of the sodium salts from III. is evaporated either in an open or in a vacuum-pan so far that a portion taken out will solidify on cooling. The contents of the pan are then run into moulds of wood or iron, and allowed to cool and solidify. The lumps are at length taken from the moulds, broken up small, and dried in a drying-room, and subsequently in a drying apparatus heated with steam, until quite desiccated.

STEP V.—The sodium sulphonate salts are now converted into their corresponding sulphonic chlorides. This is effected as follows:—The dried sulphonates are thoroughly mixed with phosphorus trichloride, itself as dry as possible. The mixture is then placed in lead-lined iron vessels, and a current of chlorine is passed over the mixture till the reaction is ended. The temperature generated by the reaction must be properly regulated by cooling the apparatus with water. The phosphorus oxychloride resulting from the decomposition is driven off, collected, and utilised for developing chlorine from bleaching powder for the chlorinating process, phosphate of lime being precipitated, which can be used in manures. For this purpose the oxychloride is treated with water, and the mixture, now containing hydrochloric and phosphoric acids, is brought into contact with the chloride of lime.

The reaction by which the ortho- and para-toluene sulphonic chlorides are produced is indicated by the following equation:—

$$C_6H_4\begin{cases}CH_3\\SO_3Na\end{cases} + (PCl_3 + 2Cl) =$$

$$C_6H_4\begin{cases}CH_3\\SO_2Cl\end{cases} + POCl_3 + NaCl.$$

Toluene sulphonic chlorides

The two sulphonic chlorides remaining in the apparatus are allowed to cool slowly, when the solid one (the para compound) is deposited in large crystals, so that the liquid one can be easily removed by the aid of a centrifugal machine. The crystalline residue is freed from all the liquid sulphonic chloride by washing with cold water. Only the liquid orthotoluene sulphonic chloride is capable of yielding saccharine, and the liquid product above separated is cooled with ice to crystallise out the last traces of the crystalline compound. The solid parasulphonic chloride obtained as by product, is decomposed into toluene, hydrochloric, and sulphurous acids by mixing it with carbon, moistening the mixture, and subjecting it under pressure to the action of superheated steam. The total change proceeds in two stages:—

1. $C_6H_4\begin{cases}CH_3\\SO_2Cl\end{cases} + H_2O = C_6H_4\begin{cases}CH_3\\SO_2OH\end{cases} + HCl.$

2. $2\left(C_6H_4\begin{cases}CH_3\\SO_2OH\end{cases}\right) + C = 2(C_6H_5 . CH_3) + CO_2 + SO_2.$

The toluene is then used again in Step I., and the hydrochloric and sulphurous acids in Step VII.

STEP VI.—The liquid orthotoluene sulphonic chloride is now converted into the orthotoluene sulphonic amide by treating the former with solid ammonium carbonate in the required proportions, and subjecting the resulting thick pulpy mixture to the action of steam. Carbonic acid is set free, and a mixture of orthotoluene sulphonic amide and ammonium chloride remains.

$$C_6H_4\begin{cases}CH_3\\SO_2Cl\end{cases} + (NH_4)_2CO_3 =$$

Toluene sulphonic chloride

$$C_6H_4\begin{cases}CH_3\\SO_2 . NH_2\end{cases} + NH_4Cl + H_2O + CO_2.$$

Toluene sulphonic amide

As the mixture is very liable to solidify on cooling, cold water is at once added to prevent this, and to dissolve out the ammonium chloride, the amide remaining in the solid state. The liquid is separated by centrifugating.

STEP VII.—The orthotoluene sulphonic amide is now oxidised, preferably by means of potassium permanganate. The result of this will be, precipitated manganese dioxide, free alkali and alkaline carbonate, and an alkaline orth sulphamido-benzoate. The alkaline liquid requires careful neutralisation during the oxidising process, and especially before evaporating, with a mineral acid, or else the sulphamido-benzoate formed would be again split up into orthosulphonic benzoate and free ammonia, thus:—

$$C_6H_4\begin{cases}CO . ONa\\SO_2 . NH_2\end{cases} + NaOH = C_6H_4\begin{cases}CO . ONa\\SO_2 . ONa\end{cases} + NH_3.$$

The oxidation process itself is thus represented:—

$$C_6H_4\begin{cases}CH_3\\SO_2 . NH_2\end{cases} + 3O + NaOH =$$

$$C_6H_4\begin{cases}CO . ONa\\SO_2 . NH_2\end{cases} + 2H_2O.$$

Sodium orthotoluene sulphamido-benzoate

By precipitation with dilute mineral acids such as hydrochloric or sulphurous acids, the pure benzoyl sulphonic imide is at once precipitated:

$$C_6H_4\begin{cases}CO . ONa\\SO_2 . NH_2\end{cases} + HCl =$$

$$NaCl + H_2O + C_6H_4\begin{cases}CO\\SO_2\end{cases}NH.$$

"Saccharine," or benzoyl sulphonic imide

Saccharine possesses a far sweeter taste than cane sugar, and has a faint and delicate flavour of bitter almonds. It is said to be 220 times sweeter than cane sugar, and to possess considerable antiseptic properties. On this account, and because of its great sweetness, it is possible that it may be useful in producing fruit preserves or jams, consisting of almost the pure fruit alone; the small percentage of saccharine necessary for sweetening these preserves being probably sufficient to prevent mouldiness. Saccharine has been proved by Stutzer, of Bonn, to be quite uninjurious when administered in considerable doses to dogs, the equivalent as regards sweetness in sugar administered, being comparable to over a pound of sugar each day. Stutzer found, moreover, that saccharine does not nourish as sugar does, but that it passes off in the urine unchanged. It is proposed thus to use it for many medical purposes, where cane sugar is excluded from the diet of certain patients, as in cases of "diabetes mellitus," and in this respect it may prove a great boon to suffering humanity, although we must remember that, as certain of the aromatic compounds if administered for a length of time are known to exert a physiological effect, especially on the liver, it will be desirable to use caution in the regular use of saccharine until its harmless action on the human body has been ascertained beyond doubt.

Saccharine is with difficulty soluble in cold water, from hot aqueous solutions it is easily crystallised. Alcohol and ether easily dissolve it. Hence from a mixture of sugar and saccharine, ether would easily separate the saccharine by solution, leaving the sugar. It melts at about 200° C. with partial decomposition.

The taste is a very pure sweet one, and in comparison with cane sugar it may be said that the sensation of sweetness is much more rapidly communicated to the palate on contact with saccharine than on contact with sugar. The speaker expressed his thanks to the discoverer of saccharine, Dr. Fahlberg, of Leipzig, for a complete and interesting series of preparations illustrating the domestic and medicinal uses of this remarkable compound, and also to his friend Mr. Watson Smith for the kind aid afforded him in the experimental illustration of his discourse.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 20.—"On the Working of the Harmonic Analyser at the Meteorological Office." By Robert H. Scott, F.R.S., and Richard H. Curtis, F.R.Met.Soc.

On the 9th of May, 1878, Sir W. Thomson exhibited to the Society a model of an integrating machine, which consisted of a series of five of the disk, globe, and cylinder integrators, which had been devised two years earlier by his brother Prof. James Thomson, and a description of which will be found in the *Proceedings* of the Royal Society, vol. xxiv. p. 262. Sir W. Thomson's paper describing this model will be found in vol. xxvii. of the *Proceedings*, p. 371; and reference should be made to both these papers for an explanation of the principle of the machine. In the communication last named it is stated that the machine was about to be "handed over to the Meteorological Office, to be brought immediately into practical work."

The model was received at the Office in the course of the

month, and was at once set in action; the results of the preliminary trials when obtained being referred to a Committee consisting of the late Prof. H. J. S. Smith and Prof. Stokes, who, on July 5 following, submitted to the Meteorological Council a favourable report on the performance of the model.

The Council at once resolved to have a machine constructed, which should be specially adapted to the requirements of the work for which it was intended, viz. the analysis of photographic thermograms and barograms.

In preparing a working design for actual execution, it was found necessary to make several modifications in the details of the mechanical arrangements of Sir W. Thomson's original model, and these were mainly worked out by Prof. Stokes and Mr. de la Rue. The construction of the instrument was intrusted to Mr. Munro. It was considered sufficient to limit the action of the machine so as to extend only to the determination of the mean, and the coefficients as far as those of the third order, in the expression

$$E = a + a_1 \cos\theta + b_1 \sin\theta + a_2 \cos 2\theta + b_2 \sin 2\theta + a_3 \cos 3\theta + b_3 \sin 3\theta + \&c.,$$

and to obtain these it was necessary to have seven sets of spheres, disks, and cylinders.

A description of the machine, as actually constructed, together with engravings giving a general view of the machine, and illustrating some of its details, will be found in *Engineering* for December 17, 1880.

The machine was delivered at the Office in December 1879, and a lengthened series of trials was at once commenced, to determine its constants, and thoroughly test the accuracy of its working, for which purpose systems of straight lines and curves, of which the values were known, were first used. A few small unforeseen difficulties were early met with, necessitating slight modifications in some portions of the instrument.

The chief of these faults was a slight turning of the cylinders upon their axes, when the balls were moved to and fro along the disks, parallel to the axes of the cylinders. The movement was always in the same direction, namely, towards the disks, whether the ball was moved to the right or left. After the trial of many expedients the defect was finally, in great measure, overcome by attaching weights to the spindles of the cylinders. It however still exists in the machine to a slight extent, and its effect is to *decrease* the readings on the cylinders by a very small amount.

It was decided to employ the analyser, in the first instance, in the determination of temperature constants, and careful comparisons have been made of the results obtained by its means with those got by actual measurement of the photographs and numerical calculations, as will presently be mentioned, and the accordance is so very close as to prove that the machine may safely be trusted to effect reductions which could only otherwise be accomplished by the far more laborious process of measurement and calculation.

It will facilitate an apprehension of the method of using the machine to give a somewhat detailed account of the operations involved in the treatment of the curves, with an example of the manner in which the readings of the machine are recorded and dealt with.

The machine is furnished with three pairs of recording cylinders and disks, numbered consecutively 1 to 6, which give the coefficients for the first three pairs of terms of the expansion, and in addition a seventh cylinder and disk from which the mean is obtained. In the thermograms which supply continuous photographic records of the march of temperature, the trace for twenty-four hours covers a length of 8·75 inches, while a vertical height of about 0·7 inch[1] corresponds to a range of ten degrees in temperature; each thermograph sheet contains the record for forty-eight hours.

Conveniently placed in the machine is a cylinder or drum, the circumference of which is equal to the length of twenty-four hours upon the thermograms. Round this cylinder the thermograms are rolled, the fluctuations of temperature indicated by the curves being followed, as the cylinder revolves, by a combination of the movement of the cylinder with that of a pointer moving in a line parallel to its axis.

The handle by which the cylinder is turned gives motion at the same time to the seven disks of the machine, and the operator thus controls by his left hand both the speed with which the curves are paid through the machine and the consequent velocity of the angular motion of the disks, while, by a suitable contrivance, the movements of the pointer, governed by his right hand and following the curve, produce on the face of the disks corresponding movements to the right or left of the balls by which the motion of the disks is conveyed to the recording cylinders.

[1] This value varies slightly for each observatory.

At the commencement of an operation all the cylinders are set to zero; the twelve months curves are then passed consecutively through the instrument; the first pair of cylinders, which gives the coefficients of the first order, and also the mean cylinder, 7, being read for each day, while cylinders 3 and 4, and 5 and 6, which give the coefficients of the second and third orders respectively, are only read for each five days and at the end of each calendar month. The numbers on the cylinders are, however, progressive, so that the increments upon them for any given period could very easily be obtained.

At present only the monthly increments of the readings have been dealt with, so as to obtain the coefficients of the mean daily variation for each month of the year. The process followed is, therefore, simply to divide the monthly increment by the number of days in the month, and then to multiply the quotient by a factor which is determined by the scale-value of the thermograms, and which will therefore be different for each observatory.

As an illustration, the case of Kew for July 1882 may be taken. The increments for the month obtained from the final readings of the cylinders are as follows:—

Cylinder	1.	2.	3.	4.	5.	6.	7.
Observed increment	+ 2·198	− 2·671	− 0·101	− 0·198	− 0·797	− 0·564	+ 56·839
Divided by 31 (the number of days).........	+ 0·071	− 0·086	− 0·003	− 0·006	− 0·026	− 0·018	+ 1·834
Factor	− 53·52	+ 53·52	− 26·76	− 26·76	− 17·84	− 17·84	+ 6·69
Coefficient deduced......... =	− 3·80	− 4·60	+ 0·08	+ 0·16	+ 0·46	+ 0·32	+ 12·27
Add constant.........							48·17
Mean temperature.........							60·44

After some trials with the curves for the year 1871, the year 1876 was taken up, inasmuch as for that year the records had been discussed by Mr. H. S. Eaton, F.R.Met.Soc., who had calculated the hourly means of the various meteorological elements for each month separately, and who kindly placed his results at the disposal of the Council.

The working of the machine was thus subjected to an exact test by comparing the results obtained by it with the coefficients in the harmonic series which were calculated from Mr. Eaton's means; and their trustworthy character, and the adequacy of these calculations to serve as a standard with which the coefficients obtained by means of the machine might be compared, was established by calculating them from the *odd* and *even* hours, quite independently, for all the seven observatories.

The outcome of this experiment was thoroughly satisfactory, and the entire series of results obtained both by calculation and from the machine was published as Appendix IV. to the Quarterly Weather Report for 1876, together with a Report prepared by Prof. Stokes, the concluding paragraphs of which may be quoted here, since they sum up in a few words the conclusions arrived at.

"Disregarding now the systematic character of some of the errors, and treating them as purely casual, we get as the average difference between the constants as got by the machine and by calculation from the twenty-four hourly means 0°·065. It may be noticed, however, that the numbers are unusually large (and at the same time very decidedly systematic) in the case of the second cylinder of the first order b_1, for which the average is as much as 0°·150, the seventh of a degree.

"If b_1 be omitted, the average for the remaining cylinders of the machine is reduced to 0°·047.

"We see, therefore, that, with the exception perhaps of b_1, the constants got by the machine for the mean of the days constituting the month are as accurate as those got by calculation, which requires considerably more time, inasmuch as the hourly lines have to be drawn on the photograms, then measured, then meaned, and the constants deduced from the means by a numerical process by no means very short."

The curves for the twelve years 1871 to 1882 inclusive have now been passed through the machine, and the results obtained have been carefully checked so far as the arithmetical work involved is concerned, upon a plan approved by the Council. No *direct* check, short of passing the curves a second time through the machine, can however at present be put on any portion of the results except as regards the means, which have been compared with the means calculated from the hourly readings obtained by measurement from the curves. The results of this work will be published in the Hourly Readings for 1883, but the general results may here be stated.

As a rule, the monthly means yielded by the harmonic analyser agree well within a tenth of a degree with those obtained by calculation from the hourly measurements of the curves; and although in some exceptional cases larger differences have been found, amounting in rare instances to as much as half a degree, it is probable that generally these are less due to defects in the working of the instrument than to other causes. In some cases large breaks in the curves, due to failure of photography, &c., were interpolated when the curves were passed through the machine, but not when the means were worked out from measurements of the curves. Some differences rather larger than usual, and confined chiefly to the earliest years dealt with, have been ascertained to have arisen from the circumstance that when the curves were first measured, to obtain hourly values, the method of making the measurements was not the same as that found by subsequent experience to be the preferable; and also that in some cases the scale-values first used were less accurately determined than has since been found possible.

In both these respects the two methods were on a par in the later years dealt with, and therefore the fairest comparison is to be had with their means.

For 1880, the average difference of the monthly mean for all the seven observatories is 0°·09; for 1881 it is 0°·05; and for 1882 0°·06; and in these three years a difference of 0°·3 between the analyser and calculated means occurred but once, and of 0°·2 but five times.

What has been said is sufficient to show that the instrument is completely applicable to the analysis of thermograms.

It has also been employed on the discussion of barograms, and the curves for the years 1871, 1872, and 1876 have been passed through the machine.

The year 1876 was selected owing to the existing facilities for comparing the resulting figures with those obtained by calculation from Mr. Eaton's means, and the result in this case was equally satisfactory with that for temperature already mentioned.

May 27.—"Family Likeness in Eye-Colour." By Francis Galton, F.R.S.

This inquiry proved that certain laws previously shown by the author to govern the hereditary transmission of stature also governed that of eye-colour: namely, that the average ancestral contributions towards the heritage of any peculiarity in a child are from each parent $\frac{1}{4}$, from each grandparent $\frac{1}{16}$, and so on; also that each parent and each child of any person will on the average possess $\frac{1}{3}$ of that person's peculiarity. The eye-colours were grouped into light, hazel (or dark gray), and dark; then it was shown that $\frac{2}{3}$ of the hazel were fundamentally light, and $\frac{1}{3}$ of them were dark, and they were statistically allotted between light and dark in that proportion. The desired test of the truth of the laws in question was thus reduced to a comparison between the calculated and observed proportion of light- and dark-eyed children born of ancestry whose eye-colours presented various combinations of light, hazel, and dark. The inquiry was confined to children of whom the eye-colours of both parents and of all four grandparents were known. There are six possible combinations of the three eye-colours in the parents, and fifteen in the grandparents, making a total of ninety possible classes, but of these one-half were wholly unrepresented in the returns, and many others were too scantily represented to be of use. The remainder were discussed in six different ways: that is to say, in two groups, *a* and *b*, and each group by three methods. In *a* the families were classified and grouped according to their several ancestral combinations of eye-colour, but only those groups that consisted of twenty or more children were used; there were 16 of these groups and 827 children. In *b* the families were treated separately, but only large families were taken, viz. those that consisted of at least six children: they were 78 in number. In both *a* and *b* separate calculations were made on the suppositions (1) that the parental eye-colours were alone known; (2) that the grandparental were alone known; (3) that the parental and the grandparental were alone known. The conformity between the calculated and the observed numbers throughout every one of the six sets of calculations was remarkably close, and the calculated results obtained by the method (3) were the best.

"Notes on Alteration induced by Heat in Certain Vitreous Rocks, based on the Experiments of Douglas Herman, F.I.C., F.C.S., and G. F. Rodwell, late Science Master in Marlborough College." By Frank Rutley, F.G.S., Lecturer on Mineralogy in the Royal School of Mines. Communicated by Prof. T. G. Bonney, B.Sc., F.R.S.

In this paper an endeavour has been made to ascertain the nature of the changes which are induced in a few typical vitreous rocks by the action of heat only. The specimens experimented upon were—

(1) The pitchstone of Corriegills, Arran.
(2) Black obsidian from Ascension.
(3) Black obsidian from the Yellowstone District, U.S.A.
(4) Glassy basalt lava of Kilauea, Hawaii.
(5) Basalt of the Giant's Causeway, Antrim.

The Arran pitchstone was heated for 216 hours at a temperature ranging from 500° to about 1100° C. The clear, greenish belonites of hornblende, so plentiful in the unaltered rock, were found to have turned to a deep rusty brown through peroxidation of the protoxide of iron which was present in the hornblende. The dusty matter mixed with clear spiculæ of hornblende, which occurred between the belonites and shaded gradually off into the clear glass which immediately surrounded the belonites in the normal state of the rock, has segregated to some extent, a sharp line of demarcation now existing between the dusty matter and the areas of clear glass, while the spiculæ of hornblende have somewhat increased in size if not in number. No actual devitrification of the glass has resulted from the heating.

The obsidian from Ascension showed only a banded structure coupled with streams of colourless microliths and a few felspar crystals when a section of the unaltered rock was examined microscopically. Two specimens of this rock were artificially heated, the first for the same period and at the same temperature as the Arran pitchstone, while the second was kept for 701 hours at a temperature ranging from 850° to 1100° C.

In the first specimen the banded structure disappeared entirely, or almost entirely, but numerous microliths are present in the altered rock, in which the most remarkahle change consists in the development of an excessively vesicular structure.

In the second specimen a vesicular structure is also developed, an outer crust consisting of a very thin layer of clear brownish glass, followed by a nearly opaque layer composed of greenish-brown microliths, which shades off into a colourless glass containing similar microliths, which are probably some form of amphibole or pyroxene. The remainder of the specimen has been completely devitrified.

The Yellowstone obsidian in its normal state shows little else but trichites and globulites when examined under a high power.

Two specimens of this rock were heated: the first at from 500° to 1100° C. for a period of 216 hours, the second from 850° to 1100° C. for 701 hours. In the first case a remarkably vesicular structure has been developed; the trichites have entirely disappeared, and small granules and crystals of magnetite have been formed. In the second specimen the changes are very peculiar. The fragment retained its original form, but the surface showed minute blisters or elevations, which, when when cracked open, revealed a cavernous structure produced by

the coalescence of vesicles averaging from ¼ to ½ inch in diameter. These cavities were often lined with a white crystalline crust, and generally contained white crystalline pellets, each about one-third the size of the cavity in which it occurred. Minute crystals of specular iron were detected upon the surfaces of these pellets. The glassy part of the rock, which still remains clear, contains trichites and globulites similar to those in the unaltered obsidian, but they are more numerous in the artificially-altered rock.

The vesicular glassy basalt lava of Kilauea, when examined under the microscope, is seen to contain crystals of olivine and minute crystallites which have not hitherto been referred to any particular mineral species. A specimen of this lava, kept for 960 hours at a temperature ranging from 750° to 1200° C., shows that the olivine crystals have undergone no appreciable alteration, but the glass itself has become perfectly opaque and black, owing to the separation of magnetite.

The specimens of basalt from the Giant's Causeway were fused in Stourbridge crucibles in a gas furnace. One, which was cooled rapidly, appears under the microscope as a clear glass containing vesicles; another, cooled slowly, is black and opaque, except in certain spots where a prismatic structure is visible, the marginal portions of the prisms having a radiating crystalline or fibrous character.

In another case some of the powdered basalt was again fused, and a fragment of cold basalt was placed on the surface and allowed to sink into the molten mass. The result was a glass, which, under the microscope, appears perfectly clear except in the immediate vicinity of the immersed fragment, which is surrounded by an opaque black border containing divergent groups of colourless transparent or translucent crystals. The black border, where it joins the clear glass, is sharply defined, and its opacity and blackness must be regarded as due to a separation of magnetite, as in the case of the altered Kilauea lava.

The first series of experiments were made by Mr. Herman. The specimens from the Giant's Causeway were experimented upon by Mr. Rodwell.

Zoological Society, June 1.—Dr. A. Günther, F.R.S., Vice-President, in the chair.—Dr. A. Günther, F.R.S., exhibited and made remarks on a specimen of a small fish of the genus *Fierasfer* embedded in a pearl oyster.—The Secretary made some remarks on the most interesting objects he had observed during a recent visit to the Zoological Gardens of Rotterdam, Amsterdam, Cologne, Antwerp, and Ghent.—A letter was read from Mr. J. M. Cornely, of Tours, C.M.Z.S., stating that his pair of Michie's Deer had bred in his park, and that a young one had been born on May 15.—Mr. Beddard read notes on the convoluted trachea of a Curassow (*Nothocrax urumutum*), and on the form of the syrinx in certain Storks.—Mr. W. F. Kirby read a paper containing an account of a small collection of Dragon-flies which had been formed by Major J. W. Yerbury at Murree and Campbellpore, N.W. India. The collection contained examples of about twenty species.

Physical Society, May 22.—Prof. Balfour Stewart, President, in the chair.—Messrs. C. A. Bell, W. C. Johnson, and James Swinburne were elected Members of the Society.—The following communications were read:—On the sympathetic vibrations of jets, by Mr. Chichester A. Bell. It has been assumed hitherto that a gaseous or liquid jet vibrates under the influence of a limited range of tones only; effective tones being those which do not differ greatly in pitch from the normal or proper tone of the jet, discovered by Savart and Sondhauss. The author has found, however, that, when the pressure under which a jet escapes is not too great, the latter is affected by all tones lower than the normal, as well as by some above it. Changes may be excited in a jet of either kind by vibratory motions of the jet orifice, or of the fluid behind or external to the orifice. These changes take the form of slight swellings and contractions, which become more pronounced as the fluid travels away from the orifice, and finally cause the jet to break or become discontinuous at a distance which depends upon the intensity of the initial disturbances. At any point within the continuous portion of the jet the successive swellings and expansions represent both the form and the relative intensities of vibrations impressed upon the orifice, and the jet is therefore capable of reproducing very complex sounds, such as those of speech and music. A vibrating jet of air does not, however, emit sound when it plays into free air, or into the wide end of a tube communicating with the ear; but when it plays against a very *small* orifice in the end of a hearing tube, loud sounds may result. This reproduction is most intense when the hearing orifice is placed in the axis of the jet, just within the breaking point, but becomes gradually feebler as the hearing orifice is moved towards the jet orifice or out of the line of its axis. Beyond the breaking point the sounds from the jet at first become confused, and finally are lost. A jet of gas, like a liquid jet, only vibrates so as to produce its normal tone when it strikes upon some obstacle which serves to diffuse the disturbances due to impact, or throw them back upon the orifice. The vibrations of an air jet are also loudly reproduced as sound when it is directed against a small flame below the apex of the blue zone. Liquid jets are but slightly sensitive to aërial sound-impulses, but become highly sensitive when the jet tube is rigidly attached to a sound-board. The vibrations of a jet so mounted are best perceived as sound when the stream strikes upon a rubber membrane tied over the end of a narrow tube which communicates with the ear. For accurate reproduction of speech and sounds in general the jets should be at such a pressure as to respond visibly to a note of about 4000 vibrations per second; and the membrane should be at such a distance from the orifice that the jet never breaks or becomes discontinuous above its surface. The vibrations of very fine jets of any conducting liquid become loudly audible when a portion of the jet, or the "nappe" formed when it strikes upon a flat surface, is included in circuit with a battery and a telephone. This may be accomplished by letting the jet impinge on the end of an ebonite rod, through the centre of which passes a platinum wire; the upper end of the rod is surrounded by a short tube or ring of platinum, the upper margin of which forms a continuous, slightly convex surface with the exposed end of the central wire and the ebonite. The wire and ring form the terminals of the circuit which is completed through the "nappe." Distilled water containing 1/300 of its volume of pure sulphuric acid is recommended as the jet liquid. The author advances a new theory to account for the growth of the vibratory changes in liquid and gaseous jets.—On some thermo-dynamical relations, part 5, by Prof. W. Ramsay and Dr. S. Young. In parts 1 and 2 of this series of papers it was shown that the ratio of the absolute temperatures of any two bodies corresponding to a given vapour-pressure bears a simple relation to the ratio at any other pressure, which may be expressed by the equation $R' = R + c(t' - t)$; where R' and R are the two ratios, c is a constant, and t' and t are the temperatures of one of the two bodies. The determination by Schumann (*Pogg. Ann.*, N.F. 12, 46) of the vapours of methyl-formate and twenty-seven homologous ethers made it possible to compare the vapour-pressures of a large number of bodies belonging to the same class. It was found that when the ethers were compared with ethyl acetate, which was taken as the standard, in every case $c = 0$, and therefore $R' = R$. The temperatures corresponding to the three pressures 260, 760, and 1300 mm. are given by Schumann. Taking the mean value of R for those pressures as correct, and recalculating the temperatures, the greatest difference between the found and recalculated temperatures is 0°·7 C. The vapour-pressures of water or any one of the ethers being accurately known, it is sufficient to determine the boiling-point of any ether belonging to this class, in order to construct its vapour-pressure curve. The absolute temperatures corresponding to the pressures 200 and 1300 mm. for any ether are ·89795t and 1·0488t, where t is the boiling-point at normal pressure in absolute temperature.—A gridiron slide-rule by Mr. Stanley, designed by Mr. Thacher, was explained by Mr. C. V. Boys. It was equivalent to a slide 60 feet long, and performed multiplication and division with an error not exceeding the 1/40,000 part.—Specimens of safety explosives and their results in shattering blocks of lead were exhibited by H. Sprengel.

Geological Society, May 12.—Prof. J. W. Judd, F.R.S., President, in the chair.—Matthew Blair was elected a Fellow, and Prof. H. Rosenbusch, of Heidelberg, a Foreign Correspondent of the Society.—The following communications were read:—On the maxilla of Iguanodon, by J. W. Hulke, F.R.S.—Notes on the distribution of the Ostracoda of the Carboniferous formations of the British Isles, by Prof. T. Rupert Jones, F.R.S., and J. W. Kirkby. Although all the Ostracoda of the Carboniferous formations are not yet described, there are 170 species and notable varieties known, belonging to thirty-three genera of nine families. About twenty-five of these species, not yet described, but determined by the authors, are introduced into

their lists as giving a fuller idea of the value of this manifold Crustacean group. In the first place they referred to the classification of the Carboniferous strata in Scotland and in England, according to the local differences, taking in succession "Scotland West," "Scotland East," "England North, with the Isle of Man," "England Central and South, with South Wales," as the several districts from which they have obtained good groups of Ostracoda from different members of the Carboniferous series. In Fife the lowest local Carboniferous strata contain *Beyrichia subarcuata*; higher up come in *Carbonia fabulina*, *C. Rankiniana*, *Bairdia nitida*, and *Leperditia Okeni*; the last, accompanied by other species, occurs throughout this lowest series, in which the record is more complete than in Midlothian and Linlithgowshire, where the same species also occur. In Dumfriesshire and Ayrshire *L. Okeni* and *L. subrecta* have been found in beds even lower than the above-mentioned, and are therefore probably the oldest Carboniferous Ostracoda; other species accompany them higher up, and in Roxburghshire some localities of the Carboniferous Sandstone series are very rich in species. The Carboniferous Limestone series of South-West Scotland has been highly productive of Ostracoda, particularly the shales of the lower beds; thirty-six species are common or characteristic. The middle or coal-bearing portion has yielded but few, chiefly *L. Youngiana*, one Beyrichia, *C. fabulina*, and *C. Rankiniana*. The Upper Limestone group contains many recurrents from below and a few others, including *Youngia rectidorsalis* (MS.). The Millstone Grit equivalents have no Ostracoda, but the overlying Coal-measures are rich in *Carboniæ*, with a few others, such as *Cypridina radiata*. A great variety of genera and species come from beds at or near the base of the Scar Limestone and its equivalents in North Lancashire, Westmoreland, Cumberland, and Northumberland. The calcareous shales of the Yoredale series have several interesting forms, including *Primitura concinna* (MS.); none from the Millstone Grit. The Lower Coal-measures give *Beyrichia arcuata* and *Carbonia*, sp. The middle beds have *B. arcuata* and *Carbonia fabulina*, common; rarer, *C. Rankiniana*, *C. secans*, *C. scalpellus*, *C. Wardiana* (MS.), and *Philomedes elongata*. In the Upper Coal-measures *B. subarcuata* reappears; and in the *Spirorbis*-limestone *Leperditia inflata* is the latest Carboniferous Ostracod in England. In Northamptonshire the deep Gayton boring (at 730 feet) has given *Kirkbya variabilis*, *K. plicata*, *Bythocypris sublunata*, *Macrocypris Jonesiana*, *Cythere lla extuberata*, and *C. attenuata*, all but one belonging to the Lower Carboniferous series. In Salop, South Wales, and Somerset the Carboniferous Limestone has yielded several good species of *Leperditia*, *Kirkbya*, *Moorea*, *Bythocypris*, *Bairdia*, &c. *Carbonia Agnes* and *C. Evelinæ* belong to the South Welsh Coal-measures. The distribution of the Carboniferous Ostracoda in Ireland requires further work; but the Lower Carboniferous Shales and the Mountain Limestone near Cork and elsewhere are very rich, as are also some parts of the latter in the Isle of Man. The Ostracoda of the Permian Formation were then treated of in relation to their Carboniferous allies, and the range of the British Carboniferous Ostracods in Europe and North America was noticed in some detail. The results of the examination were shown in two extensive tables.—Note on some Vertebrata of the Red Crag, by R. Lydekker, F.G.S. This communication contained briefly the results of a re-examination of the specimens from the bone-bed of the Red Crag in the British and Ipswich Museums, a series of casts from the latter having been added to the former. The forms noticed were *Hyæna striata*, with which *H. antiqua* and *H. arvernensis* were considered probably identical, *Mastodon*, of which the author thought three species—*M. arvernensis*, *M. longirostris*, and *M. borsoni* were represented; *Sus*, of which two forms, the larger probably *S. erymanthius* or *S. antiquus*, the smaller *S. palæochœrus*, had been detected; a Tapir, which was probably *Tapirus arvernensis* or *T. elegans* rather than *T. priscus*; *Hipparion gracile*; a *Rhinoceros* referable to the hornless *R. incisivus* rather than to *R. schleiermacheri*, though the latter probably also occurred; and a species of Albatross (*Diomedea*) represented by a right tarso-metatarsus, and the associated proximal phalangeal bone of the fourth digit.—The Pleistocene succession in the Trent Basin, by R. M. Deeley, F.G.S. The beds of the lowest division were distinguished from those of the middle and upper by the absence of Cretaceous rock-debris. Older Pleistocene: Early Pennine Boulder-clay, Quartzose Sand, Middle Pennine Boulder-clay; Middle Pleistocene: Melton Sand, Great Chalky Boulder-clay, Chalky Sand and Gravel; Newer Pleistocene: Interglacial River-alluvium, Later Pennine Boulder-clay. Each of the separate stages was then described separately, with details of exposures and sections throughout the area.—On the existence of a submarine Triassic outlier in the English Channel off the Lizard, by R. N. Worth, F.G.S.

Anthropological Institute, May 25.—Francis Galton, F.R.S., President, in the chair.—Mr. Reginald Stuart Poole read a paper on the ancient Egyptian classification of the races of man. This was defined by the famous subject of the four races in the tombs of the kings at Thebes (B.C. 1400 1200). The types were (1) Egyptian, red; (2) Shemite, yellow; (3) Libyan, white; (4) Negro, black. By comparison with monuments of the same period and of a somewhat earlier date, the first race, clearly an intermediate type, was seen to comprehend the Phœnicians, the Egyptians, and the people of Arabia Felix with the opposite coast. The Libyan race included an aquiline type, with marked supra-orbital ridges and receding foreheads, as well as a straight-nosed type. These two types inhabited the south coast of the Mediterranean, and some of the islands. The Negro race included the Negro and Nubian types. The Hittites and Hyksos, or shepherds, were as yet unclassed. Prof. Flower pointed out the resemblance of the aquiline Libyan type to that of the Neanderthal crania, and the oldest European type, and saw in the Hyksos head distinctly Mongolian characters. These two points are of the highest consequence in historical anthropology.—Mr. C. W. Rosset exhibited a large collection of photographs and other objects of ethnological interest from the Maldive Islands and Ceylon.

Paris

Academy of Sciences, May 31.—M. Jurien de la Gravière, President, in the chair.—Observations of the small planets made with the large meridian instrument at the Paris Observatory during the first quarter of the year 1886, by M. Mouchez.—Note on a new general method of determining directly the absolute value of refraction at all degrees of altitude, by M. Lœwy. This is a further development and more general application of the author's recent communication on the means of determining some absolute values of refraction with a sufficient degree of accuracy.—Researches on the densities of liquefied gases and of their saturated vapours, by MM. L. Cailletet and Mathias. In this memoir the authors' studies are limited to the protoxide of nitrogen, ethylene, and carbonic acid. It is shown that at the critical point the density of the fluid is equal to that of its vapour, whence a practical means of determining graphically the density at the critical point when the critical temperature is known. It is also shown that the expansion of the liquefied gas is greater than that of the gas itself. The methods here described are applicable to all gases whose critical point is higher than the freezing-point of mercury.—On MM. Albert A. Michelson and Edward W. Morley's recent experiments to ascertain the influence of motion of the medium on the velocity of light (*American Journal of Science*, May 1886), by M. A. Cornu. The author briefly describes the American physicists' experiments, which show that the result announced by Fizeau in 1851 is essentially correct, and that the luminiferous ether is entirely unaffected by the motion of the matter which it permeates. At the conclusion of the paper M. Fizeau took occasion to remark that he had never ceased to prosecute his studies on the nature and properties of the ether, and hoped soon to announce the existence of a peculiar variation in the magnetic force of magnets apparently in relation with the direction of the earth's motion through space, and calculated to throw great light on the immobility of the ether and its relations to ponderable matter.—On an arc tangent to the solar halo of 46°, observed on May 30, by M. A. Cornu. Of the numerous halos observed during last month this is described as the most remarkable. It was visible towards 5 p.m. under the form of an extremely vivid iridescent arc concentric with the zenith at a distance of 15° to 20° in a circular sphere of from 60° to 80°. The author considers that from the systematic observation of these phenomena some valuable data might be obtained regarding the condition and movements of the upper atmospheric currents, which would be useful in weather forecasting.—On the heats of combustion and of formation of the solid carburets of hydrogen, by MM. Berthelot and Vieille. The method announced by the authors two years ago for measuring the heat of combustion of the fixed or but slightly volatile organic compounds is here applied to the study of naphthaline, acenaphthene, anthracene, phenanthrene, dibenzyl, and some other

carburets chosen on purpose with a view to determining certain general relations.—On the ammonia present in the ground: a reply to MM. Berthelot and André, by M. Th. Schlœsing. The points in dispute are re-stated, and the author deals fully with the chief objections urged by MM. Berthelot and André against his view that generally speaking the ammonia passes from the atmosphere to the earth.—Note accompanying M. Silvestri's report on the eruption of Mount Etna on May 18 and 19, by M. Daubrée. It is noticed that the present lava-stream, like that of 1883, flows from the crevasse which was opened on the flank of the volcano in the direction from north-east to south-west in the year 1875. But it rises at an elevation of about 1400 metres some 7 kilometres above the town of Nicolosi, which has thus so far escaped destruction.—On the influence of magnesia on Portland cements, by M. G. Lechartier. The author's extensive researches amongst public buildings and structures of all sorts fully confirm the conclusion already arrived at by Rivot regarding the destructive effects of the magnesia present in these cements. The more they are exposed to the direct action of water, the more rapid is the process of decay.—Observations of the new comet Brooks III., made at the Observatory of Nice with the Gautier equatorial, by M. Charlois.—Note on the theoretic calculation of the composition of vapours, their coefficients of expansion, and vaporising heats, by M. M. Langlois. The formulas which in the author's theory give the specific heats of the gases or vapours are as under:—

	Atm.		
Molecules at	1	... ...	$C = \frac{2}{3}\frac{V\pi Pg}{9}\alpha = \frac{2}{3}A\alpha$
,,	2	... ...	$C = A\alpha$
,,	3	... ...	$C = \frac{4}{3}A\alpha$
,,	4	... ...	$C = \frac{6}{3}A\alpha$

where α is the coefficient of expansion of the vapour, V the volume occupied by 1 kilogramme of this vapour under the pressure F. The complete theory will be explained at the next Congress of the French Association at Nancy.—On the diffusion of heat and physical isomorphism, by M. L. Godard. The property of being athermochroic, hitherto supposed to be peculiar to pure common salt and sylvine (natural chloride of potassium), is shown to be also characteristic of the isomorphous and anhydrous chlorides, bromides, and iodides. These substances have the same chemical formula and crystallise in the same system, and thus is once more confirmed the analogy presented by the physical properties of isomorphous bodies.—Law of the product corresponding to the maximum of useful work in an electric distribution, by M. Vaschy. It is shown that Jacobi's law (product $= \frac{1}{2}$) is inapplicable to the case of a dynamo-generator whose electromotor force is a function of the current traversing it.—On the cyclonic whirlwind of May 12: influence of the Guadarama mountain-range on its progress through the Iberian peninsula (second note), by M. A. F. Nogués. The fresh impulse given to this Atlantic cyclone by contact with the cold dry upland currents in the neighbourhood of Madrid show that under special conditions the central Spanish plateau may be compared to certain tropical regions, producing in Spain meteoric phenomena analogous to those of the torrid zone.—On the heats of combustion of the fatty acids and of some fatty substances derived from them, by M. W. Louguinine. Completing his previous studies on the heat of combustion of the fatty acids and their derivatives, the author here treats of caprylic, nonylic, lauric, myristic, and palmitic acids, and of the trilaurine and trimyristine glycerines.—On the dissociation of the carbonate of lime, by M. H. Le Chatelier.—On a new gaseous body, the oxyfluoride of phosphorus, with the formula $PhFl_3O_2$, by M. H. Moissan.—On the direct chloridation of methylbenzoyl, by M. H. Gautier.—Action of oxygenated water on benzoic acid in the presence of sulphuric acid, by M. Hanriot. Having previously shown that oxygenated water reacts on the benzenic hydrocarburets in sulphuric solution, transforming them to phenols and diphenols, the author here extends this reaction to the aromatic acids, and especially to benzoic acid.—On jaborine, by MM. Hardy and Calmels.—Absorption of the bicarbonates of potassa and lime by the roots of beetroot during the first year's growth, and their transformation to organic acids in combination with the potassa and lime diffused throughout the different parts of the plant during vegetation, by M. H. Leplay.—On the superficial measurement of the underground parts of plants, by M. Aimé Girard. A method is proposed by which the superficial development of vegetable roots may be approximately determined within about $\frac{10}{100}$ above or below the reality.—Fresh observations on the Jurassic bilobites, by M. Stan. Meunier. Several new forms of these curious fossil vestiges are described, tending more and more to show that they are of organic origin, and not merely animal footprints.—On the existence of the Lower Eocene formation in the Chalosse district, and on the position of the Bos d'Arros strata, by MM. Jacquot and Munier-Chalmas.

EARTHQUAKES AND OTHER EARTH-MOVEMENTS

Earthquakes and other Earth-Movements. By J. Milne. "International Scientific Series," Vol. LVI. (London: Kegan Paul, Trench, and Co., 1886.)

THE object of this work is "to give a systematic account of various earth-movements": these are classified as (1) Earth-quakes, (2) -Tremors, (3) -Pulsations, and (4) -Oscillations, which are severally defined as (1) sudden or violent, (2) minute, (3) slow, (4) secular movements of the ground. The earthquakes occupy 305 pp., whilst only 43 pp. are given up to the other three motions. After an introduction follows a description (22 pp.) of about twenty different kinds of instruments for recording earth-movements (seismo-scopes, -meters, and -graphs), beginning with an ancient Chinese seismoscope (A.D. 136). The construction of a proper seismo*graph* which shall record period, amplitude, and direction of movements is difficult, the inertia of the moving parts masking the earth-movement. A set of tipping columns seems to be the simplest seismoscope, and some form of pendulum the simplest seismograph: these can be made "astatic," so as to retain any deflected position. Of recorders of motion a smoked-glass plate seems the simplest. The "Gray and Milne seismograph" is an elaborate instrument, recording continuously and simultaneously the times, and also the three rectangular components, of any displacement.

The explanation of earthquake propagation by waves of elastic compression and distortion, shadowed forth by Dr. T. Young, is fully discussed and illustrated for the general reader: the former are compared to sound-waves and the latter to light-waves; unlike these, however, the direct waves travel the quicker. It appears that about seven-eighths of the speed of wave-transit through homogeneous rock is lost in actual rocks as found *in situ*.

Experiments on artificial earthquakes have—as might be expected—been few. Only three sets appear to have been published. Those by Mr. Mallet (published in 1851) were based on explosions of large masses of powder up to 12,000 lbs. Those by General Abbot in America (published in 1876) were based on explosions of from 70 to 400 lbs. of dynamite. Those by Mr. Milne in Japan, since 1880, were based on the fall of a ton weight through from 10 to 35 feet, and on explosions of 1 to 2 lbs. of dynamite. The general conclusions are that the wave-speed is quicker for direct than for transverse vibrations, is quicker through hard than through soft rock, increases with increase of the shock, and decreases with distance. It is clear that opportunities for experiment on the effect of explosions such as the above must often occur, and that a small expenditure on seismographs alone is needed to embrace the opportunities.

There appears to be no known limit to the frequency and duration of earthquakes. Shocks occur continuously in the Andes (p. 246), and have lasted for weeks in New Zealand at the rate of 1000 a day (p. 72). Continuous shaking has been *felt* in Japan during 4½ minutes (p. 73). Recorded vibration-periods vary from two-tenths of a second to one second, and the amplitude may amount to 1 foot without rupture. Some calculations are given of *velocity* of motion of the ground derived from fall of buildings and projection of copings, caps, &c.: these are open to large error from omission of resistance to fracture and of friction. The conclusions as to the rate of earthquake propagation agree with those derived from the artificial earthquakes quoted above.

The most practically useful chapter is that on effects on buildings (a subject recently discussed at the Institution of Civil Engineers), as to which the most important conclusions are—(1) local knowledge alone will guide to the safest site; thus hills, valleys, plains, hard strata, soft strata, &c., are each safe in some, unsafe in other countries. (2) If the direction of shocks be definite, place the blank walls parallel, and the pierced walls perpendicular thereto. (3) Openings at different levels in the same wall to be échelonned. (4) Avoid flat arches, or place wood lintels over them. (5) Avoid heavy copings, caps, &c., and tall chimneys. (5) Use roofs of low pitch. (7) Structures of different vibration-period should not be connected.

Structures of bamboo and timber are seldom injured by earthquake-shock directly; earthquakes are only indirectly destructive to them through fires (caused by the upsetting of lamps) and floods (which sometimes follow).

The earthquake-effects on land are the opening of cracks and fissures, with occasional discharge of water, mud, &c., landslips, and disturbances of lakes, rivers, &c.; also upheavals and depressions of whole tracts: these are —with the exception of the last—seldom extensive. The chief effect on the ocean is the raising of a great sea-wave, sometimes very large, *e.g.* 60 feet high at Lisbon (1761), 80 feet at Callao (1724), 210 feet at Lupatka (1737). These waves are often more destructive on land than the actual shocks; the influx is usually preceded by an outflow, which in fact acts as a warning. One of the most remarkable effects is the distance to which these waves are propagated as "great waves," *e.g.* right across the Pacific. Thus most large earthquakes on the east or west coasts of the Pacific produce waves which are recorded on the opposite coast about twenty-four hours after. From the recorded time of transit of these waves and the known distance the average depth of the ocean (supposed uniform) can be calculated by Russell's formula ($v^2 = gh$); the calculated depths are generally less than the soundings (which err necessarily in excess).

As to source of earthquakes eight methods are given for finding the "epicentrum" or *surface*-origin, and four for finding the "centrum" or *actual* origin, on various assumptions: *e.g.* radiation from a point (viz. the epicentrum), uniform propagation, homogeneous strata, &c. Results depending on such doubtful assumptions can only be very rude approximations.

As to distribution over the world, it appears probable that all parts of the world have been shaken at various times, but that in the historic period the regions most

liable to earthquake are those near to active or recently active volcanoes, especially the Pacific border (which actually contains 172 out of a total of 225 now active volcanoes); also earthquakes are propagated chiefly *along* valleys or ridges.

The distribution of earthquakes in time has been much discussed, but no periodic law either secular, seasonal, or diurnal, either for the world in general or for any one place, is very clear.

After discussing the synchronism of earthquakes with numerous physical phenomena (positions of heavenly bodies, states of air, &c.), the causes of earthquakes are considered, and the conclusion is drawn that the primary causes are probably terrestrial, such as (1) sudden cracks consequent on over-stretching of the earth's crust during elevation; (2) explosions of steam; (3) collapse of hollows produced by volcanic ejection and by the continuous solution and removal of matter by springs; (4) change of load over large areas due to rise and fall of the tides and to changes in air-pressure.

As to prediction of earthquakes, nothing certain is yet known. In many cases there are noticeable changes in springs and wells preceding earthquakes. One useful warning is, however, obviously possible, viz. the report of an actual earthquake on one side of the Pacific could be at once telegraphed to the other side, thus giving twenty-four hours' warning of the probable advent of a great sea-wave.

As to earth-tremors, two curious cases are quoted: (1) the extra crowds of people in Greenwich Park on public holidays cause extra shaking in the Greenwich Observatory instruments; (2) certain delicate observations projected at Cambridge in 1880-82 proved futile in consequence of the continuous earth-tremors masking the delicate effects sought. To these might now be added in London the tremors produced by the Underground Railway. Systematic record of earth-tremors (micro-seismography) has now been made in Italy in many towns for ten years: these tremors appear to be periodic, and to be connected with the sun's and moon's motions, and with the state of the barometer, and to increase *before* earthquakes, so that there is some hope of possibility of earthquake prediction from this research.

The phenomena of earth-pulsations and -oscillations quoted are numerous and interesting, but space fails to enumerate them.

The work begins with an earthquake-map, and ends with a list (10 pp.) of earthquake-literature.

This work is well worthy of its place in the International Scientific Series, and may be accepted as a monograph on its subject by an accomplished seismologist, who, from his residence in Japan, has had ample opportunities of studying the actual phenomena.

ALLAN CUNNINGHAM, Major, R.E.

FRICTIONAL ELECTRICITY

Frictional Electricity. By Thomas P. Treglohan. (London: Longmans, Green, and Co., 1886.)

THIS is a little book written for first beginners in the study of electricity. On the whole it is satisfactory; although the writer betrays curious want of knowledge or want of judgment here and there. The diagrams are good, and the descriptions fairly clear; and from place to place instructions are given to teachers as to experiments they may make before elementary classes for the purpose of illustrating and bringing home to the learners the various parts of the subject. The construction of simple pieces of apparatus, such as a boy may make for himself, is also described throughout the book and in a number of paragraphs at the end.

There are, however, certain points to which we take serious exception. First, we cannot regard Mr. Treglohan's mode of looking at inductive phenomena as correct or satisfactory. For example, speaking of the electrophorus, he says: "If, while the conductor rests upon the excited cake and is under the inductive action of it, the upper surface of the conductor be touched by the finger, the free negative passes to the earth, and an equal quantity of positive enters the disk from the earth." The same statement is made on the following page, so that there is no doubt whatever that the statement about the "equal quantity of positive" is really meant. In the diagrams throughout the book too, where discharge as the result of induction is going on two little arrows are shown, one marked + and the other −, and pointing in dissimilar directions. This seems to us particularising with a vengeance the action of two fluids.

On p. 35, under the heading "specific inductive capacity," we are told that "It was established by Prof. Faraday that, for an excited body to act upon a conductor by induction, some substance must exist between the two through which the electricity may be imparted." Shade of Faraday!

At the end of this paragraph, speaking of specific inductive capacity, we are told that "dry air is superior to moist air in this respect." We do not think that any difference has been proved to exist between dry air and moist air, either as to induction or as to conduction; though there is a common misapprehension (shared by the present author, p. 30) of a difference as to this latter quality.

The use of the condensing electroscope seems to be misunderstood by the author. It cannot be used in the way described for testing "lightly charged bodies." Its main use is for testing a weak but continuous source.

There is also an extraordinary paragraph about a white-hot iron ball on p. 107, for which the author seems to make Prof. Guthrie responsible, and in which the experimenter is told to put a white-hot iron ball on the electroscope in order to prove certain statements! We fear the experimenter will not obtain much valuable information from the experiment; and it is *not true* that, with respect to the supposed indifference of a white-hot body to electrification, "in this it resembles the indifference to magnetism of a white-hot iron ball."

A few misprints we have also noticed. Sir William Thomson's name should be spelled without a "p"; iodine and starch paper is coloured blue, not brown, by ozone. Putting aside these defects, however, this little book will probably be found useful to teachers for the elementary stage in the Science and Art Department, for whose benefit, as we are told in the preface, it has been compiled.

J. T. B.

OUR BOOK SHELF

The Gallery of Marianne North's Paintings of Plants and their Homes, Royal Gardens, Kew. Descriptive Catalogue compiled by W. Botting Hemsley, A.L.S. Fourth Edition. Pp. 160. (London: Printed under the Superintendence of Her Majesty's Stationery Office, and sold at Kew Gardens, 1886.)

THIS is a much enlarged and improved edition of the previous excellent catalogue of these valuable and interesting paintings. The whole collection having been rearranged and as many as 220 additional paintings added, the value of the catalogue, as may be supposed, is considerably enhanced, and the more so as many of the new paintings are the result of Miss North's more recent travels in such noteworthy countries as the Seychelles. The description of each of the pictures, with notes on the habits and uses of the plants represented, are both interesting and useful, the whole being carefully condensed within reasonable compass, but beyond this the present edition is made doubly useful by the addition of a most carefully drawn up list of plants referred to in the catalogue, arranged alphabetically under their natural orders, together with the native country of each species. The sketch of the "general features of the vegetation of the countries visited" is a most valuable addition, each country being treated of separately. These are, as Mr. Hemsley says, "short paragraphs describing the prominent features and peculiarities of the vegetation of the various countries whose floras are illustrated with some degree of fulness therein." Thus, under Chili we have first a general description of its position, character, climate, and meteorological conditions, followed by notes on the vegetation, with references to the more important genera. This part of the book, which forms the introduction, and extends to thirty-one pages, will be extremely useful to all students of geographical botany; indeed the whole book has a value besides that of a mere "guide" to the visitor to the gallery.

We cannot conclude our brief notice of this excellent catalogue without referring to another important feature in this edition, namely, the introduction of a really good map of the world, showing in red the countries visited by Miss North, and in green other floras partially illustrated in the collection.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Thomson Effect

IT affords me much satisfaction to find that my statement of the facts of the Thomson effect is in the main accepted by Prof. Tait. The errors to which I called attention had been copied into at least one recent electrical text-book, and were in a fair way to obtain general recognition as fundamental principles.

The only objection which Prof. Tait raises to my statement is my omission to include a correction for the variability of one of the coefficients with temperature. This is no valid objection, as the limits of space forbade me to encumber my explanation with any unnecessary detail, and my mathematical investigation was avowedly only approximate. The correction thus supplied by Prof. Tait and embodied in his equation (1) is to the effect that, in flowing through a copper conductor, the electric current, while displacing the whole temperature curve in the forward direction (as stated by me), displaces the maxima more than the minima, so as to make the descending gradients steeper and the ascending gradients less steep, the displacement of each point being proportional to its absolute temperature. In iron the same rule holds except that "backward" must be substituted for "forward." Prof. Tait agrees with me that the ordinates are not increased or diminished, but are simply shifted. The current does not tend to diminish the difference between maxima and minima, as a real fluid would do.

The phrases "electric convection of heat" and "specific heat of electricity" have served their purpose, as provisional terms, furnishing a short and easily-remembered way of expressing certain new facts, which would have required for their full expression a long periphrasis; but to retain them any longer in our text-books is to place a needless stumbling-block in the way of teachers and students.

Let Thomson's coefficient σ (hitherto called the specific heat of electricity) be called the *Thomson coefficient*, and let the numbers tabulated by Prof. Tait under the heading "Specific Heat of Electricity" ("Heat," p. 180) be called *tangents of slope*, a name which speaks for itself when the meaning of a thermo-electric diagram is understood. The Thomson coefficient will thus (in the ordinary case) be equal to the absolute temperature multiplied by the tangent of the slope; and the amount of the Thomson effect between two given temperatures will be their difference multiplied by the Thomson coefficient for the mean temperature.

A good name is wanted for the ordinate of any point in a thermo electric diagram. In the first edition of "Units and Physical Constants," being driven to give it some name, and not being able to think of a good one, I employed the makeshift term, "thermo-electric value." In the forthcoming edition I propose to denote it by the more appropriate name, "thermo-electric height." J. D. EVERETT

Belfast, June 12

Black Rain

THE heaviest shower on record fell yesterday afternoon between 6 and 7 p.m. It began at 6.36, and almost six-tenths of an inch fell in the first quarter of an hour. The wind was shifting rapidly at the time from north through west to south. The water collected was very dark, but not so black as that which fell on April 26, 1884. S. J. PERRY

Stonyhurst Observatory, June 10

Meteor

YESTERDAY (Sunday), June 13, at 10.12 p.m., looking eastward, I saw a magnificent meteor, extremely brilliant, darting from southward to northward, at an altitude of about 30°. It must have been a minute or two in view, as I had time to stop walking and watch it describe a long track. When it had passed the prime vertical it burst into a shower of sparks which, falling in a second or two, became invisible. The colour of the meteor was intense white, with a bluish tinge in rear, and only a very slight trail was visible. On exploding the light was crimson for an instant, and the sparks were red.

Should you receive any other notices of this meteor, its height, distance, and magnitude may be computed. It seemed to me of the diameter of a cricket-ball. I have never seen so large a meteor before, or any describe so long a path. The memorable meteor-shower of 1866 (?) exhibited none so large, though possibly many had longer tracks. You may hear of it from the North Sea. R. STRACHAN

11, Offord Road, London, N., June 14

"Arithmetic for Schools"

MR. LOCK is a little loose, not to say unfair, in the drawing of his inferences; I prefer, therefore, to stand by my own words.

(1) When I said "the purely arithmetical part" (not Part) of the book, I meant what I said, viz. those sections where such *theoretical* matters as the finding of the highest common factor, the extraction of the square root, &c., are treated of. The possibility of any reader of NATURE drawing the inference which Mr. Lock succeeds in drawing, viz. that the book is expressly divided into Pure Arithmetic and Practical Arithmetic, is surely a very trivial matter.

(2) At p. 181 the following definition occurs:—"Rate of interest is the ratio of interest to the principal." This I gave as an instance of "slight inaccuracy." It may be a fundamental misconception, and not a slight inaccuracy; but if so Mr. Lock

has no cause for complaint. He ought to know that interest is a function of two variables.

(3) In reply to Mr. Lock's request for other slight inaccuracies I might ask, without leaving the subject of interest, what under the sun "inverse interest" is: but though inaccuracies of language are not desirable in a school-book, I prefer to draw his attention to more important matters. Every arithmetician knows that the practical questions which come under such headings as Simple and Compound Interest, Exchange, Discount, Stocks, &c., are not questions of a different kind *arithmetically*, being all so-called "proportion" questions, and that no more important fact can be taught to the student of arithmetic regarding them. Now here is Mr. Lock's treatment. Simple and compound proportion questions are put under the headings "Problems" and "Complex Problems"—names, by the way, quite illogically chosen and not consistently adhered to. Exchange is tacked on to Complex Problems by the words, "examples in Exchange can be worked by the above method"—indeed, these words and a worked example constitute the sum total of information given in the book on this subject. No one could object to the union here indicated, but surely the same is equally true of several of the other subjects. After Exchange comes a section headed "On Problems concerning Time: I., Time and Distance." These are not problems in the sense previously specified, but belong to the genus of examination questions which concern bodies moving in the same path with different speeds. A like remark applies to the section which follows, headed "II., Time and Work." Late in the day, after Interest, Discount, &c., there appears a chapter "On the Use of the Term *Per Cent.*" So far as it is on anything (for it consists of seven or eight lines of introduction, three worked and forty-five unworked examples), it is on the calculation of rates of gain and loss. Now all this, one is bound to affirm, is strangely illogical, and tends to give a most erroneous conception of arithmetic as applied to practical affairs. I used the expression "slight inaccuracies of thought" in referring to such a mode of treatment, because it was impossible to be more severe without going into detail, and because it seemed imperative to say something against a practice, which our examination system fosters, of forming text-books by collecting all the kinds of exercises met with in examination papers and separating them into carelessly ticketed groups prefaced by a definition or two. The purely arithmetical, and larger, part of Mr. Lock's book is not of this character, and is, especially as regards the definitions, very carefully prepared; he would considerably enhance the value of the whole by wisely modifying the rest in the second edition.
THE REVIEWER

I THANK you for your courtesy in permitting me to see the reply of your reviewer to my letter which appeared in NATURE of June 3 (p. 100). That my letter was written under very exceptional circumstances will be clear to any one who will take the trouble of comparing your reviewer's defence of his criticism with the book itself. I will, however, with your permission, make one or two comments on his reply.

(1) That a wrong inference was suggested by the words of the reviewer is, no doubt, of little consequence, except that it afforded me a ground for an appeal to you for further information.

(2) Your reviewer did not quote in his review, as he now does, my definition of rate of interest; he asked whether rate of interest is totally independent of the time, implying that I stated that it was so, and ignoring the fact that the manner in which time is involved in Interest (not in *rate* of interest, on which point your reviewer seems a little confused) is gradually explained in the next few pages. Might I ask your eviewer whether in Compound Interest the Interest varies simply as the Time?

(3) In his third paragraph your reviewer gives his answer to my request that he should quote *verbatim* the other instances on which he based his unfavourable criticism. There is little or nothing here for me to answer, except that I am compelled, in justice to myself, to point out the reviewer's own mistakes. (i.) He suggests that Exchange ought logically to be placed between Compound Interest and Discount. It would seem necessary to remind him that in questions on Exchange there is no reference to *time*, and that it is the peculiar manner in which time is involved, which distinguishes Interest and Discount from other Problems involving money. (ii.) He states that questions which I have called "Problems concerning Time" are improperly so-called. It will be clear to any one who reads the chapter on "Problems" that a Problem is a question on Variation; so that problems concerning time are exactly what their name indicates. But (even supposing your reviewer were right on these two points) in charging me with being strangely illogical as regards the order of my chapters, he must have overlooked the fact that in the preface I expressly state that "novelty in arrangement has been avoided as much as possible," but that "the order in which his chapters are taken may be varied at the discretion of the teacher." For my part I think that the established order of subjects is not to be lightly upset, certainly not without more sound and weighty reasons than those adduced by your reviewer.

But besides this your reviewer draws an unfair inference, due I suppose, to mere carelessness. The words "Inverse Interest" appear only as the heading of pp. 187, 188, and are obviously an abbreviation for convenience of printing of the words on p. 186, "Inverse questions on Interest." As far, however, as I can understand the general effect of your reviewer's explanation, his objection to my book seems to be this—that it fails to bring into sufficient prominence the fact that the Practical Applications of Arithmetic (which, in accordance with established custom, I have collected under the heads of Exchange, Problems concerning Time, Interest, Proportional Part, &c.), really present the same idea under different circumstances, expressed in different language. I entirely agree with him as to the importance of this fact, and endeavoured, as far as the scope and object of my book would allow, to give it due prominence. For example, for this reason, it seemed unnecessary in Exchange and in the chapter on Profit and Loss to give more than a few words of explanation in addition to the examples worked out.
JOHN B. LOCK

Gonville and Caius College, June 14

PASTEUR'S RESEARCHES

IN the current number of the Royal Agricultural Society's *Journal* (vol. xxi. part 1) is a full and able account of the work of the great French experimenter from an agricultural and veterinary point of view, by Dr. George Fleming. The development of Pasteur's genius is traced from his early chemical researches on dextro- and lævo-tartrates to fermentations in milk and in malt. The combination of microscopic with chemical modes of investigation led him to the definite determination of the part played by living organisms in acetic, butyric, and alcoholic fermentations. In these inquiries his own labours were almost entirely original, but it must not be forgotten that a few microscopists in England and many in Germany were working on the same lines, and contributed to the establishment of the modern doctrine that fermentation and putrefaction are both processes dependent on the presence and growth of minute parasitic plants. Pasteur's experimental investigations led him in two directions—in one to the establishment of the now accepted theory of biogenesis: that every living thing is the product of a living parent; in the other to the practical application of the facts ascertained to the manufacture of vinegar and the process of brewing.

Ingenuity in devising experiments and patience in carrying them to a successful issue belong more or less to every successful investigator, but the union in addition of clear theoretical conceptions with skill in the useful application of results is characteristic of Pasteur as it was of Faraday and a few other of the highest intellects.

His investigation into the cause of *pébrine*, or silkworm disease, was undertaken against his will, in deference to the urgency of the eminent chemist Dumas. Pasteur wished to return to his original department of chemistry, and it is remarkable that having once left it he has been drawn further and further into biological researches, while Dumas, who began with valuable work on the development of the ovum, was diverted to chemistry and there made his enduring reputation. Perhaps no instance more remarkable than Pasteur's work on the *pébrine* can

be cited of the value of science in a commercial and national point of view. A great industry was all but extinguished, and the impending catastrophe became a question for parliaments and statesmen. A scientific investigator was appealed to; he set to work in 1865, and after four years' continued application he had solved the problem, and delivered his country from the incubus on her industry. It has been well said that Jenner by his discovery of vaccination saved more lives than Napoleon ever destroyed; so Pasteur saved France in 1869 from a far greater tribute than the Prussian conqueror imposed on her in the following year.

This brilliant success, which could be neither concealed nor depreciated, led to the successful experimenter (barely recovered from an attack of paralysis, which ended his last laborious research) being called on to devise a means of checking the ravages of splenic fever (*anthrax*) among horses and cattle. Dr. Fleming gives an interest-account of this terrible scourge, and explains the methods adopted by Pasteur to investigate it. He discovered a method by which its virus may be "attenuated," and thus used for protective inoculation in the same way as vaccination protects against small-pox. This method, though often successful, has not proved uniformly so, and more must be done before its general efficiency is established. Dr. Fleming refers to the results in Algeria, in Prussia, and in Hungary, and to these he might have added those obtained by Dr. Roy in Buenos Ayres.

On the other hand, the treatment by inoculation of a contagious disease among poultry (ill-named *choléra des poules*), a method which was also discovered by Pasteur, appears to be uniformly successful.

The last investigation of the great French experimenter is that upon hydrophobia, which the world is still anxiously watching. This also is described by Dr. Fleming. We have kept our readers informed of the progress of this vast practical trial of a scientific mode of treatment on the victims of a hopeless malady. Every month brings fresh accumulation of evidence on the subject, and we hope soon to have the report of the Commission sent from this country to ascertain M. Pasteur's precise methods and their results. If he should be honoured to be an instrument in the hands of Providence for averting one of the most shocking and terrible diseases to which mankind is subject, the name of Pasteur will live as one of the greatest benefactors of our race. But in any case his work already achieved and its results established form an ample title to the admiration and the reverence of all who can estimate genius or value its conscientious devotion to the service of mankind.

LYCOPODS[1]

THE attention of the readers of NATURE has already been directed towards recent work on the Lycopodiaceæ by the publication of a *résumé* of the researches of Dr. M. Treub, Director of the Botanic Gardens of Buitenzorg, Java. He is the first botanist who has succeeded in giving a connected account of the prothallus, sexual organs, and development of the embryo of any species of Lycopodium, and now his first paper, which dealt with *L. cernuum*, has been rapidly followed by a still more complete and successful study of *L. Phlegmaria*, L. It might be expected that the second paper would be in great measure a repetition of the first, but this is not so; and it may be regarded as one of the most interesting results of this very suggestive and luminous investigation that it brings into prominence the greatness of the possible differences in development of two plants which have hitherto passed, and will continue to pass, under the same generic name. The observations detailed in this second paper are so important in their bearings on our views regarding other allied forms that it is desirable that at least the more striking points should be recorded here.

[1] "Études sur les Lycopodiacées," par M. Treub. Part II. *Annales du Jardin Botanique de Buitenzorg*, vol. v. 2ième partie.

Attempts to germinate the spores of *Lycopodium Phlegmaria* were at first unsuccessful, but after more than a year young plants were found on one of the tree trunks on which spores had been sown, and subsequently similar young seedlings were found in large numbers in the forest. The germination of the spores appears to be slow, and Dr. Treub is of opinion that the culture of prothalli from spores will never be easy, a view which is supported by the fact that the oophore is capable of various modes of asexual multiplication; indeed it appears that the majority of the prothalli found owed their origin to this source, and not directly to the germination of spores. An autonomous existence of the prothallus, independent of the formation of sexual organs, has been demonstrated by Goebel in the case of *Gymnogramme leptophylla*, and a similar, but still more pronounced condition is found in this Lycopod. The prothallus grows in the dead external layers of the bark of trees; it is as a rule devoid of chlorophyll, and consists of cylindrical branches, covered with absorbing hairs. These cylindrical organs branch monopodially, the branches being usually formed in acropetal order; they have a terminal growth with two initial cells, each of which gives rise to half of the cylindrical organ. It is worthy of note that there is a great similarity between the structure of this apical meristem and that of the stem of the sporophore. In the fully-differentiated parts of the prothallus a peripheral tissue one layer of cells in thickness may be distinguished; this gives rise to the rhizoids. The mass of tissue inclosed by this superficial layer, though it shows some slight varieties according to the mode of development of the branch, never attains any high state of differentiation.

The lateral branches, which are not very numerous, take their origin from the peripheral layer, several cells taking part in the formation of each. The growth of these branches may be long-continued, and it is not arrested on the formation of an embryo on another branch. By progressive rotting of the older parts branches may be separated from one another, and this constitutes the simplest mode of increase in number of individuals But, besides this, two other modes of vegetative propagation are known—(*a*) by ordinary propagating organs: these are small ovoid multicellular bodies, which originate from single superficial cells, and are set free by rupture of their pedicels; (*b*) by thick-walled organs, smaller than the above, which only appear on weakly prothalli: these may undergo a period of rest. Among the vascular Cryptogams the only organs hitherto known of a similar nature to these are those described by Cramer; Dr. Treub is, however, of opinion that a truer comparison may be be made to the gemmæ of the Hepaticæ, and especially of *Blasia*, while in many of their general characters, which may be recognised on inspection of the twenty beautiful plates, the prothalli of *L. Phlegmaria* show points in common with the oophore of certain of the Muscineæ.

The sexual organs of *L. Phlegmaria* are produced on the upper surface of the prothallus, and are always accompanied by paraphyses, structures which are absent in other Vascular Cryptogams, but frequently present in the Muscineæ. The position of the antheridia is variable; sometimes they are scattered singly on the vegetative branches, sometimes they are associated in groups, and are then often borne on the considerably thickened extremities of branches. Their development is similar to those of *L. cernuum*, while the antherozoids have two cilia, and resemble those of *Selaginella*. The archegonia have a more definite position, and they appear subsequently to the antheridia, on those thickened extremities of branches which have already borne antheridia: they project from the surface of the prothallus, and have three to five canal cells, while the highest number hitherto recognised

among Vascular Cryptogams is three; this is again a point in common with certain Muscineæ.

This would not be the place to enter upon those details of the mode of development of the embryo, which Dr. Treub has worked out with such signal success. It must suffice, while referring those who are specially interested in the subject to the original paper, to state merely the most prominent facts. In the first place there is a considerable difference between the development of the embryo in *L. cernuum*, and that of *L. Phlegmaria*, while in certain points the latter corresponds to *Selaginella Martensii*. Thus the ovum in *L. Phlegmaria* divides first by a wall perpendicular to the axis of the archegonium into two: of these, the cell next the neck becomes the suspensor, the other is the mother-cell of the embryo; the latter develops ultimately into a multicellular mass arranged in two tiers: the lower tier forms only the massive "foot," while from the upper (*i.e.* that further from the neck of the archegonium) are derived the stem and single cotyledon, and ultimately also the first root. The mode of origin of the root is interesting in connection with my own recent observations of the exogenous origin of the root in Phylloglossum. According to Dr. Treub's observations, the first root of *L. Phlegmaria* is at first covered by an envelope a single layer of cells in thickness, which cannot rightly be regarded as the outermost layer of the root-cap; accordingly we have the barest possible example of endogenous formation, only a step removed from the exogenous. These and other results of the investigation of the development of the embryo of *L. Phlegmaria* afford fresh material of the greatest value for comparison, not only with other groups of the Vascular Cryptogams and with the Muscineæ, but also with other species of the genus Lycopodium. Further, the full account given of the prothallus provokes a comparison which Dr. Treub has embodied as follows (p. 88):—"As far as it is possible to judge at present, we find in the sexual generation of the Lycopods, more clearly than elsewhere, transitional terms between the great series of the Muscineæ and that of the Vascular Cryptogams." Some readers will doubtless call to mind, in connection with this, a striking passage by a well-known botanist, Prof. Goebel, written a few years ago (Schenck's *Handbuch der Botanik*, Bd. ii. p 401), which runs thus:—"We must then satisfy ourselves by asserting that the gulf between the Mosses and Pteridophyta is the deepest that we know in the vegetable kingdom, and bridging it over by hypotheses and explanations does not make it one whit the less."

In this treatise of Dr. Treub we are put in possession of those positive observations which, beyond their intrinsic and independent interest, acquire the highest possible value from the fact that they fit into this wide and deep gulf, and materially help to fill it up. Such observations, and the theoretical considerations which follow them, are sure of a hearty welcome among the fellow-countrymen of Charles Darwin.

I cannot close this article without a brief reference to the peculiar case of symbiosis found in the prothalli of *L. Phlegmaria*. Endophytic Fungi have already been described in prothalli of other species, and here Dr. Treub finds the tissues constantly infested by a fungus, apparently one of the Peronosporeæ. Its thin filaments inhabit the interior of the cells themselves, but without killing them, the nuclei of the cells remaining normal, while the growth of the prothallus does not appear to be visibly hindered by its presence. It would appear that we have here a case of "commensal" symbiosis, in the strictly literal sense; unfortunately it is impossible as yet to follow out the subject thoroughly into its details, but we may hope that Dr. Treub may be able shortly to give us some more general insight into the economic relations of the two organisms thus amicably associated together.

F. O. BOWER

THE UNITED STATES FISHERIES[1]

THESE two volumes, with the familiar black cloth binding, shiny paper, and plates of photo-engravings, characteristic of American official publications, are the first instalment of a series, which is to contain the results of an exhaustive survey of the United States fisheries from all possible points of view. The purpose and method of the survey, and the history of its origin and progress, are sketched in a prefatory note by Mr. Spencer F. Baird. In 1879 it was arranged that the Tenth Census, which is under the direction of General Francis A. Walker, should co-operate with the Commission of Fish and Fisheries in carrying out an historical and statistical investigation of the fishery industries. The direction of the whole survey was intrusted to Mr. G. Brown Goode, Assistant Director of the National Museum, who had for some years previously devoted a large portion of his time and energies to the study of the fisheries. The work to be carried out was divided by Mr. Brown Goode into seven departments:—(1) Natural history of aquatic products; (2) the fishing grounds; (3) the fishermen and fishing towns; (4) apparatus and methods of capture; (5) products of fisheries; (6) preparation and manufacture of fishery products; (7) economy of the fisheries. The co-operation of every person who had any special knowledge of the subjects under consideration was secured. The field-work was so divided that each portion could be assigned to men who were most competent from their previous experience to undertake it. The shad and alewife fisheries, for example, were assigned to Colonel Marshall MacDonald, the Alaska fisheries to Dr. T. H. Bean.

It was understood from the beginning that the results obtained should be set forth in a series of finished reports, of which those referring principally to the exploited organisms, namely, fish and aquatic animals, should be presented to and published by the Fish Commission, while those dealing with the exploiting organisms, the fishermen and manufacturers, should be the property of the Census Office. The expenses of the work have been shared between the Commission and the Census. The reports prepared for the Fish Commission being too bulky for publication in the annual reports, permission was obtained from the Senate and House of Representatives to publish them separately. The series will be as follows:—Section i. natural history of useful aquatic animals (the two volumes now before us); ii. the fishing grounds; iii. the fishing towns; iv. the fishermen; v. the apparatus of the fisheries and the fishing vessels and boats; vi. the fishery industries; vii. the preparation of fishery products; viii. fish culture and fishery legislation; ix. statistics of production, exportation, and importation; x. the whale fishery; xi. a catalogue of the useful and injurious aquatic animals and plants of North America; xii. a list of books and papers relating to the fisheries of the United States; xiiii. a general review of the fisheries, with a statistical summary.

The statistical reports prepared for the Census Office are ten in number. The results they contain have been already partially published in Census bulletins and in statistical tables scattered here and there in various volumes. The prefatory note concludes with a brief summary of the statistics of the fisheries. In 1880 the number of persons employed in fishery industries was 132,426, of whom 101,684 were fishermen. The total value of the capital invested was $37,955,349.

After the prefatory note we find the letter of transmittal from Mr. Brown Goode to Prof. Baird. In this it is stated that the work is intended especially for the use of the reading public, and technical zoological discussions

[1] "The Natural History of Useful Aquatic Animals of the United States," forming Section i. of "Fisheries and Fishery Industries of the United States." 1 vol. Text; 1 vol. Plates. 4to. (Washington, Government Printing Office, 1884.)

and descriptions have not therefore been included. On another fly-leaf is a list of the authors who have had a share in the production of the work. The number of these is no less than twenty, and among them are such familiar names as Tarleton H. Bean, John A. Ryder, and R. Edward Earll.

The work is divided into five parts: i. mammals; ii. reptiles and batrachians; iii. fishes; iv. mollusks; v. crustaceans, worms, radiates, and sponges. Of the mammals the whales and porpoises are described by G. Brown Goode; seals and walruses, by Joel A. Allen, and Henry W. Elliott, who contributes a chapter on the life-history of the fur-seal; manatees and the Arctic sea-cow, by Frederic W. True. The reptiles and batrachians are also treated by Mr. True. Mr. Brown Goode is responsible for the greater part of the portion dealing with the fishes. The part on mollusks consists of two chapters, one on mollusks in general, by Ernest Ingersoll; one on the oyster, by John A. Ryder. Part V. is the work of Richard Rathbun.

The work of Mr. Brown Goode is always lucid, systematic, and complete. In his account of the whales and porpoises he does not give technical zoological diagnoses, these being, as we have already mentioned, intentionally omitted throughout the work, but he gives the accepted name with its authorities accurately indicated. He describes fully, with references to all the literature of the subject, the distribution, habits, food, and reproduction of all the species having an economic value. Figures of nearly all the species are given; these are taken from various sources, some prepared specially for the present work, some copied from the plates of existing zoological memoirs.

A discrepancy occurs between the title of one of the figures and the description contained in the text: the porpoise sperm whale is stated to have been described by Prof. Gill, under the name *Kogia Floweri*, while the figure given is entitled *Kogia Goodei*, True, the pygmy sperm whale. Two sketches illustrating the whale fishery are reproduced in Plates 3 and 10. The account of the "right whales" is not altogether clear. It takes some time to find out that the species generally known as the "right whale" is *Balæna mysticetus*, L., which is the Arctic whale, or bowhead; while the true right whale is Eubalæna, Cope: but the assertion that *Eubalæna cisarctica*, Cope, is not remotely related to *Eubalæna biscayensis* of the Eastern Atlantic, remains a puzzle.

Mr. Allen's work on the seals is thoroughly satisfactory, and the history of the fur-seal at the Pribylov Islands, given by Mr. Elliott, contains the results of accurate personal observation, which has at last elucidated the meaning of the peculiar and long-known habits of this species. The movements of *Callorhinus ursinus* when absent from its breeding places remain for the present obscure, but the reason why it seeks its breeding places so regularly, and the facts of its reproduction—knowledge of which is necessary in order that a permanent diminution of the numbers of the animal may be avoided—are clearly set forth in this essay.

The illustrations of the account of the seals and of Mr. Elliott's essay are particularly good. Among the former are two maps of the world, showing at a glance the geographical distribution of the useful seals. Mr. Elliott's original sketches of the fur-seal at home in the Pribylov Islands are very spirited and interesting.

Mr. True gives an account of the South American manatee, and reviews lucidly the history of the extinct Rhytina of Behring's Strait.

The chapter on the reptiles and amphibians is entirely unillustrated, for what reason does not appear. The reptiles which afford products useful to man are the alligator, the turtles and tortoises, and one frog—*Rana catesbiana*, Shaw—the bull-frog. This last animal is cultivated in several localities, the eating of the hind-legs being common in most towns of the States.

The note at the commencement of Part III. on the food-fishes is a little inconsistent. "We anticipate the criticism that the book is of no use in identifying the different kinds of fish, by the statement that we expressly desire that it shall not be," is one sentence; and another is, "Most of our important species can be identified by reference to the plates." What the writer evidently means to say is that each species mentioned is accurately figured and receives its correct technical name, so that any one interested in fishes can find out the zoological name of his specimens from the plates, and can read all about range and economical uses, while for more detailed scientific treatment reference must be made to speciegraphical works in ichthyology. Various ichthyologists have contributed to this portion of the work. The fishes of the Pacific coast are the special province of David S. Jordan, while one or two species, like the Californian salmon and the carp, have been allotted to pisciculturists specially familiar with them. Many vexed questions in the biology of fishes are discussed by Mr. Brown Goode with his usual lucidity and comprehensiveness. The pages on the reproduction of the eel, for example, are very interesting reading, and this is by no means a solitary example. The food-fishes naturally take up a large portion of the whole work. They occupy more than half of the volume of text, extending to more than 500 pages. In the plates there is one feature which we have after serious efforts completely failed to understand. On nearly every plate there is a straight line below each figure, apparently intended as some standard of measurement; but the meaning of these lines is not explained.

In his chapter on the mollusks Mr. Ingersoll has not always observed the rule strictly followed in the rest of the work of giving the authority for each specific name used. He gives an account of the distribution of the numerous other species of Lamellibranchs used as food in the United States, but gives no description of oyster-beds. In Mr. Ryder's account of the life-history of the oyster there is a great deal of interesting detail about anatomy and development, and about the writer's own experiments in oyster-culture, but a general account of the distribution of *Ostrea virginica* is wanting. This is a surprising omission, and one much to be regretted.

Why Mr. Rathbun, even in a work intended for general readers, should unite together Echinoderms and Cœlenterates as Radiates is a question which it would be difficult to answer. The name Radiata would require to be considered in a history of zoology, but it is impossible to justify its use in the classification of animals for any purpose in the present state of science. But this and the other slight defects we have pointed out do not make a very great reduction in the value and completeness of the whole work. The labour spent in its preparation has been very great, and the result is a lasting monument to the industry and scientific capacity of Mr. Browne Goode and his numerous fellow workers.

REMARKS ON THE EGGS OF BRITISH MARINE FISHES[1]

THE majority of marine fishes, in regard to reproduction, readily range themselves into certain groups according to the condition of the eggs on deposition. Thus (*a*) a considerable number have delicate pelagic ova, which are generally separate, though in the frog-fish, for instance, they form gelatinous masses. (*b*) Others are characterised by the deposition of thick-walled ova, connected together in more or less firm masses, on or near the bottom, or in special nests. (*c*) A third group is distinguished by laying ova which have filamentous processes or adhesive surfaces for attachment to foreign structures; and some place them in brood-pouches of the males, in which case, however, the capsules appear to be

[1] By Prof. McIntosh, F.R.S., &c., St. Andrews Marine Laboratory.

more delicate. (*d*) A fourth series have their large eggs enveloped in dense horny capsules, which either are fixed by their twisted filaments to marine bodies or find sufficient protection on the extensive sandy flats where they are deposited. (*e*) Finally, a few produce living young, this condition ranging from the well-marked ovo-viviparous *Zoarces* to the even more complex state in the sharks.

It would seem, as far as present observations go, that in those fishes which shed their eggs on the bottom, or in brood-pouches, the ova are matured simultaneously in the ovaries, so that the act of deposition is performed rapidly. This is exemplified in the *Cotti*, in *Agonus* (*Aspidophorus*), *Cyclopterus*, *Liparis*, the herring, and others. In the case of fishes with pelagic ova, on the other hand, the ovaries mature and shed their contents at intervals, so that the process of spawning occupies a period of greater or less duration.

There is little difficulty in the case of the pelagic ova of our shores, such as those of the cod, haddock, whiting, bib, ling, rockling, gurnard, and others in artificially impregnating and hatching them, even from fishes that have been dead for some hours. The mortality, however, from excessive cold and heat is very considerable in a marine laboratory, since the limited quantities of sea-water contained in vessels a foot or even a yard or two across are much more subject to such influences than the vast body of water in the sea. It has to be borne in mind also that the sea-water usually employed in such researches is shore-water, and liable to considerable contamination from the estuaries of rivers and streams—besides other impurities. The difference, indeed, between such water and that of the open sea was illustrated in 1884 (NATURE, vol. xxxi. p. 536), when the pelagic ova of the cod could be more successfully hatched in the large glass vessels ("drop" bottles) in which they were conveyed from the fishing-ground without change, than in the ordinary water dipped from the shore and frequently renewed. In like manner eggs of plaice fertilised on the same ground this year (for which I have to thank Capt. Burn, of St. Andrews) were conveyed quite safely, even after a week's vicissitudes in a stoneware jar amongst sea-water—lightly tied over with "cheese" cloth. During the late winter ova of various kinds suffered severely, however, and the effects of such changes of temperature on the embryos were even more pronounced.

The first series of eggs of the haddock were fertilised on the 15th, and the second on the 16th of February, but the rigorous weather proved ultimately fatal to both. The earlier stages proceeded satisfactorily, but the water in the vessels by and by was frozen on the surface —softish flakes of ice forming a thick coating—on which many of the ova were elevated. No sooner was this ice broken than all or almost all the ova were observed to present the whitish patch and sink to the bottom. Some of those which had floated in mid-water or under the trickle from the supply-pipe escaped destruction, but in a few days they also succumbed after a night of unusual severity, and after the embryos had been outlined. On the other hand, a few ova carelessly thrown at the same period into a small vessel of sea-water in the window of a library escaped injury and developed quickly, though the water remained unchanged.

In the sea the danger from such extreme cold would be minimised, since these pelagic eggs in winter and spring do not float quite at the surface, but always some distance beneath it.

Under the same circumstances in the laboratory the intense frost proved fatal to many adult viviparous blennies and Montagu's suckers, though only the surface of the sea-water in the large glass vessels was coated with the softish flakes of ice. The fluid in the ovaries of the pregnant examples of the former was frozen into a solid mass, as was also the liquid in the urinary bladder, yet the animals were surrounded in all cases by sea-water.

In the Report to H.M. Trawling Commissioners in 1884 reference was made to the statement by Alex. Agassiz (*Proceed. Americ. Acad. of Arts and Sci.* xvii. p. 289, 1882) that the ova of several species of *Cottus* float. In his recent beautiful memoir along with Whitman (*Mem. Mus. Comp. Zool.* xiv. part i. 1885), he again returns to the subject—giving figures and descriptions of the ova of the so-called *Cottus grœnlandicus*, Cuv. and Val., which he found in a pelagic condition abundantly during the summer months, especially in July. The authors, indeed, appear to have met with the ova only on the surface of the sea, and do not seem to have identified them with those in the ovary of the species indicated, which in our country is supposed to be only a variety of *Cottus scorpius*, L. Unless, therefore, the *Cottus grœnlandicus*, C. and V., of Prof. Agassiz, is a form very different, there is room for doubt in regard to this interpretation of its oviposition.

The spawning of the *Cotti* in this country wholly diverges. Instead of the issue of the eggs in detachments, as in most fishes with pelagic eggs, the ovaries of the *Cotti* become distended at the breeding-season with ripe eggs of a uniform size, which are generally deposited in a mass at once—along with a transparent mucous secretion. When ejected into the water the eggs adhere together, but at first they can hardly be lifted on account of the soft and yielding nature of the connecting medium, though they do not readily separate. In a few hours the hardening of the connecting medium and the egg-capsules stiffen the outer layers of eggs, but the central region is still soft. The process of hardening is thus somewhat slow, and apparently depends on free contact with sea-water. These eggs are comparatively large and thick-walled, as well as slow in development, the embryo being ushered into the world in a much more highly organised condition than in the embryos from pelagic eggs. There is, indeed, little resemblance between Agassiz's form and the young *Cottus*, which is considerably larger, is variegated with much pigment, has rudimentary lamellæ (papillæ) on the branchial arches, complex circulatory organs, and a small yolk-sac possessing a single large oil-globule; and it shoots upward into the surrounding water like the young *Liparis* and *Cyclopterus*.

While the newly-hatched *Cottus* therefore greatly surpasses Agassiz's type in complexity, there are certain marine forms, *e.g. Anarrhichas*, which as greatly surpass *Cottus*. This will be evident when it is mentioned that the strongest embryos of the wolf-fish are much more highly developed on their escape from the egg than the salmon is for a week or two subsequently. Artificial stocking of the sea with the valuable food-fishes, such as the cod and haddock, would have been comparatively easy if their ova and embryos had been as readily handled and reared. However, since a noteworthy increase in tenacity has been observed in certain forms as soon as the yolk-sac has been absorbed, there is room in this respect for further investigation.

THE HONG KONG METEOROLOGICAL OBSERVATORY[1]

THIS first-class meteorological observatory was erected in 1883, and the regular work of observing began on January 1, 1884. Weather Reports appear monthly, and we have now before us the observations and work of Mr. Doberck and his staff for the first two years. For the first two months the work was restricted to eye-observations, but meanwhile no time was lost in erecting the barograph, thermograph, anemograph, pluviograph, and sunshine recorder, which are similar to those in use at Kew; and from April 1, 1884, the Monthly

[1] "Observations and Researches made at the Hong Kong Observatory in the Years 1884 and 1885." By W. Doberck, Government Astronomer.

Reports include a continuous hourly record of the more important elements of the climate of Hong Kong. The buildings are erected on the peninsula of Kaulung, facing the harbour, on the top of Mount Elgin, a small eminence rising from the plain to a height of about 110 feet above mean sea-level. It may also be noted that the ground has been carefully turfed where the instruments are placed. In addition to the usual tabulations and their averages, the Monthly Report gives a carefully observed log of non-instrumental phenomena, such as dew, fog, unusual visibility, halos, and thunderstorms.

The results show that the amplitude of the daily range of the barometer is greatest from November to February, when the rainfall is least and the air driest, the mean difference during these four months between the morning maximum and afternoon minimum amounting to 0·102 inch. On the other hand, the mean of the four months from June to September, when the monthly rainfall nearly equals 12 inches, only amounts to 0·069 inch. The diurnal range of temperature is small, being for the year only 5°·5, the maximum, 7°·2, occurring in December, and the minimum, 4°·0, in February. The daily minimum occurs at all seasons shortly before sunrise, and the maximum from 1 to 2 p.m. during the dry season, but an hour later during the wet season. The hourly means for the tension of the aqueous vapour are very interesting, as showing very clearly for those months when the sunshine is daily practically constant and the air relatively dry a minimum period during the hottest hours of the day; whereas when the sunshine is much interrupted, the rainfall frequent, and the air moist, the daily maximum tension occurs at these hours.

For the twelve months beginning March 1884, the greatest amount of sunshine was from noon to 2 p.m., and the least from 4 to 5 p.m., the former being per hour nearly double the latter. During the 22 months the greatest monthly number of hours of sunshine for any hour of the day was 26·3 hours from 9 to 10 a.m. of October 1884 out of a possible 31 hours. From midnight to noon the mean monthly rainfall has been 4·98 inches, but from noon to midnight the amount has only been 2·73 inches. The four consecutive hours of largest rainfall are from 5 to 9 a.m., amounting to 1·91 inch, and the four consecutive hours of least rainfall from 8 p.m. to midnight amounting only to 0·76 inch, or considerably less than half the former time of the day. The diurnal period of the rainfall of Hong Kong is remarkable as showing the maximum fall during the period of rising temperature, and the minimum when temperature is rapidly falling, the amounts for the six hours ending noon being 2·66 inches, and for the six hours ending midnight 1·24 inch. Future observations will doubtless modify in some degree the curve of daily rainfall, but from the general accordance of the fall of the individual months with what is indicated above, it is not likely that the change of the curve will be very material.

The daily curves for the winds, both as regards velocity and direction, are very decided. The daily curve for wind velocity has, for Hong Kong, owing to its peculiar position with reference to the island and the continent, peculiar features of its own. Thus for the year the maximum velocity extends from 10 a.m. to 2 p.m., the means for these four hours being the same, while the minimum velocity extends from 6 to 10 p.m., the hour of least movement being from 7 to 8 p.m. From midnight the wind rises to the daily maximum at 10 a.m. The month of greatest force of wind is March, and of least August, the air-movement in the former month being nearly double the latter. As regards direction the wind is about E.N.E. in the winter and E.S.E. in the summer season. For the whole year, the mean direction is E. 3° S., and the diurnal variation from E. 5° N. at midnight to E. 15° S. at noon, the mean variation being thus through 20°. During 1884 the total distance travelled by the wind was 103,237 miles, and of these 63,349 miles, or more than half the whole, was east wind. The least frequent wind is N.W., which showed only 2053 miles.

At a distance of about two miles from the Observatory an important station has been established on Victoria Peak, at which observations are made at 10 a.m. and at 4 and 10 p.m., and the results are published *in extenso* in the Monthly Report. The height of this station is 1823 feet above sea-level. These two almost contiguous stations, the higher being on a peak and the lower also on an eminence sloping directly down to the sea, form an admirable pair of stations for furnishing, in the best procurable form, the observational data necessary for some of the more important physical inquiries of meteorology. So far as we are aware, no pair of stations can be placed side by side with Hong Kong Observatory and Victoria Peak as affording the data for the physical inquiries referred to, except Ben Nevis Observatory and the station at Fort William.

Of these inquiries the important practical question of the rate of decrease of temperature with height may be cited as an example. The remarkable suitability of these two groups of stations for advancing this inquiry lies in the circumstance that in each case the upper station is situated on a true peak, thus reducing to a minimum the influence of the land in changing the temperature of the winds before arriving at the Observatory; and that the lower station is on a rising ground near the sea and sloping down to it, thus minimising the disturbing effects of radiation. At Hong Kong the rate of decrease of temperature with height is 1° for 261 feet in winter; 347 feet in spring; 262 feet in summer; 254 feet in autumn; and 281 feet for the year. At Ben Nevis the rates are for the seasons 279, 251, 268, and 290 feet, and for the year 270 feet—the results being thus closely accordant. On the other hand, such a pair of stations as Obirgipfel in Austria, on a peak 6706 feet high, and the neighbouring station at Klagenfurt, 1437 feet high, cannot furnish the data necessary to this inquiry owing to the circumstance that the lower station is situated in a deep valley. The result is that in January the difference of the mean temperatures of the two stations is less than 1°, although the one is 5269 feet higher than the other; whereas in May the difference of their mean temperatures is 22°·0.

It is earnestly hoped that the publication *in extenso* of the hourly observations at Hong Kong will not be limited to ten years, as seems to be hinted at in the Report, but that the meteorological observations and their publication will be made a permanent part of the work of the Observatory. The unique position of Hong Kong with respect to the great continent of Asia and its meteorology will no doubt secure this object.

CHOLERA IN ITS RELATION TO WATER-SUPPLY

THE epidemic of Asiatic cholera, which has been raging in Spain during the last two years, and which appears even yet to be lurking in some portions of that peninsula, has furnished some interesting data as regards its connection with water-supply, to which it would be wise in us to direct our attention, not only from the interesting nature of the facts as such, but also because it is not improbable that ere the disease quits Europe it may visit our own shores.

Broadly speaking, it would appear that in Spain this formidable disease never became truly epidemic or dangerous in any city in which there was a pure and good supply of water, and proper means were taken to guard against the sources being polluted by any of the specific choleraic poison.

In support of this idea I would desire to call attention to the cities of Toledo, Seville, Malaga, and Madrid, in contradistinction to such places as Aranjuez, Saragossa, Granada, and Valencia. I will commence with Madrid.

This city, whose population at the last census was 397,816, suffered very severely indeed under the last epidemic of 1865, when during several days immediately following a very severe thunderstorm the number of cases varied from 800 to 1200 per day. The first invasion of last year took place in Madrid on May 20, and the disease ran its course during the whole of the summer, gradually disappearing towards the end of the month of September. The total number of cases during the whole of the period was 2207, and the deaths 1366. The total number of cases, therefore, during the five months that the disease never abandoned the city was barely more than what occurred during two days only of the epidemic of 1865, being little more than ½ per cent. of the population. I think, therefore, we may safely say that the disease never assumed a truly epidemic form. The greatest number of cases, as was to be expected, took place during the months of July and August; the first notable increase took place on July 25, and the first notable decrease on August 13.

In connection with this it is interesting to note that Madrid was subject to severe thunderstorms during the latter end of July, and that 119 millimetres of rain fell during the month. These storms began on the 13th, and were especially severe on the 23rd, 24th, 26th, 27th, and 31st, the first notable rise in the cases of cholera occurring between the 25th and 28th. As a general rule, no rain falls in Madrid in July, and the occurrence of these severe thunderstorms and heavy falls of rain was quite phenomenal.

The new water-supply from the Guadarama Mountains was completed shortly before 1865, and the greater part of the drainage was also finished; but at that time the new water supply had scarcely come into use, the large majority of the houses being supplied from the old fountains which existed in various parts of the city. During the last twenty years the use of the Lozoya water has become very general, and an ample supply has been provided for washing the streets and flushing the sewers.

Madrid is now well drained; the sewers are built upon the Paris model, and are not what an English engineer would consider as a good type for self-cleansing purposes, but the fall is, in almost every case, very great, and it is not probable that there can be any collection of fœcal matter at any point. The connection of the street gulleys with the main sewers is made without any trap, and good ventilation is thus provided. As regards the outfall of these sewers, nothing satisfactory can be said. The mouths of the main sewers, which are seven in number, all discharge on the southern side, between the station of the Saragossa Railway and that of the Northern.

The question of the proper disposal of the sewage in Madrid, as in London, has never been decided, and pending this decision the sewers were completed only as far as the outlying houses of the city, and the sewage was then allowed to find its way down to the Manzanares, in the best way it could. During the time the question has been awaiting a solution the town has extended, and houses have been built along the course of these open sewers. As might have been expected, the first serious outbreak of cholera occurred about these spots, the original germ of the disease having been imported from the neighbourhood of Valencia, where the cholera was then raging.

The existence of the disease having been established beyond doubt, one of the first acts of the Municipality was to attend to the water-supply. There existed 12 ancient sources, which supplied 85 taps or fountains, 22 of which were public ones, at which water-carriers were allowed to fill their barrels, and the remaining 63 belonged to groups of houses. In spite of the excellent supply brought in from the Lozoya, these old sources were still a good deal used by the inhabitants—many, from old habits, preferring to use the same water which their fathers had used, many not being willing to incur the expense of laying on the new supply. In view of the impossibility of effectually guarding against the possible contamination of so many sources of supply, the Municipality, by decree on June 18, closed all the old ones with the exception of that of La Fuente de la Reina, which supplied five public fountains and four private ones. The Central Government undertook the custody of the Lozoya aqueduct, the Municipality took charge of the Fuente de la Reina. The Lozoya water is drawn from the sources of the River Lozoya in the Guadarama Mountains, some 50 miles to the north of Madrid.

The river takes its rise in the granite formation; the water is excellent, and from the uninhabited condition of the country through which the river flows before the intake, it is not exposed to direct contamination from any specific poison. From the intake to Madrid the water is conducted by a series of magnificent works, partly covered, partly uncovered, to Madrid, where it is received in covered reservoirs before being distributed in the city; the service is continuous, no cisterns being used. During the whole time of the existence of cholera in the city the uncovered portion of the aqueduct was patrolled by armed guards, no one being permitted to approach without a special order.

Accompanying the extensive Report of the Mayor of Madrid, Don Alberto Bosch, amongst other plates is an excellent map of the city, showing, by a red dot, the situation of every case of cholera that occurred; they are seen pretty thickly scattered about the uncovered exits of the sewers, and on both sides of the River Manzanares—which is, in fact, in summer an open sewer—and in the lower portion of the city overlooking the river, and there is scarcely any part of the town where a dot is not to be found; but, with the exception of the points mentioned, the cases occurring in the remainder of the town seem to be all isolated ones; in extremely few cases do two dots occur together, showing that the disease was more of a sporadic than of an epidemic character.

Now let us take the case of Toledo. This ancient capital of Spain is certainly not a city that could be taken as a model of sanitary arrangements; on the contrary, it seems to be admirably adapted to form a good nest for any wandering epidemic, and yet, although the cholera entered it in the summer of 1884, and did not finally leave it till the autumn of 1885, the total number of cases, according to official returns, did not exceed 200, of which about one-half were fatal. The population of Toledo is over 20,000, so that the percentage of choleraic disease was only about 1 per cent. of the population for the two seasons.

Toledo was supplied with water from the River Tagus, which flows round the city, the water being lifted by pumps. Above Toledo, on the same river, is situated Aranjuez, and above Aranjuez again, on the Manzanares, which is a feeder of the Tagus, is situated Madrid, in both of which towns the cholera existed in 1885, being unusually severe in Aranjuez. The Governor of the province, recognising the suspicious character of the water, stopped the pumps, and obliged the inhabitants to send for their drinking-water to a distant spring; he even forbade any one to bathe or wash clothes in the river. The measure was a strong one, but it saved the city.

Let us next take Seville. Seville is an important city, the third in rank in Spain; it contains, according to the census of 1877, 134,318 inhabitants; it has, strictly speaking, no drainage; a few ancient sewers exist for carrying off the rain-water from the lower portion of the city, but sewerage for houses does not exist. The sewage goes into cesspools, which are, in most cases, situated just outside the house, and under the street; the inhabitants are extremely cleanly in their habits, and the outsides of their dwellings are constantly whitewashed, but it is not

a healthy city—typhoid fever is endemic, and the death-rate rises in some parishes to 35 per mil.

Seville is situated on the River Guadalquiver, of which the Rivers Darro and Genil, that flow through Granada, are feeders; as regards its water-supply, one suburb of the city, called Triana, containing about 30,000 inhabitants, is situated on the western side of the river. This portion is almost entirely inhabited by the poorer class, and they drink generally the water of the river.

The rest of the town is supplied from an ancient Roman or Moorish aqueduct, the water being brought from an underground spring near the town of Alcalà, about nine miles to the east of Seville; this water is carried by a tunnel about two miles in length under the town of Alcalà; it is then carried in a covered conduit to within a short distance of Seville, and from thence by an aqueduct made by the old Moors. The water is excellent.

An English Company has quite lately erected engines at Alcalà, by means of which they pump up to a covered reservoir above the town the water from two other springs, situated also at Alcalà, but on the opposite side of the river Guadaira, which flows past the town. This water is carried from the reservoir into the town by iron pipes, and distributed under considerable pressure; in character it is pure and excellent; the springs rise from the base of the sandstone at a short distance from the engine-house, and are carried across the river by an iron pipe. The cholera broke out in Granada on July 14, 1885, but already on June 14 of the same year the authorities of Seville, by way of prevision, had prohibited the use of any water from the river, either for dietetic or other purposes; had authorised the English Company to lay a temporary pipe across the bridge which connected the city with the Triana suburb, and had opened a number of free taps from which the inhabitants of this suburb could draw the new water.

The old Moorish supply was scarcely susceptible of contamination, as the conduit was covered for the greater part of the way, and where it ran over the aqueduct no one but the Municipal guards had ever been allowed to pass; guards, however, were stationed day and night on the springs from which the English Company derived their water, and no one was allowed to approach them without permission.

The cholera raged fearfully in Granada during the months of July, August, and September; it descended the River Genil, which runs through Granada, and attacked the towns of Herera, Ecija, and others in the province of Seville. It broke out also at Cordova and other towns on the Guadalquivir, of which the Genil is an affluent, and it broke out in Palma, Utrera, Puerto Real, Puerto Santa Maria, and Cadiz, forming a circle round Seville, but the city itself escaped almost completely. Towards the end of September nine cases occurred in one quarter of the city, of which seven were fatal, but the disease did not spread; none of the five houses in which these cases occurred were connected on to the water-supply, and it is possible they may have used well or river water, although this is not known. Jerez, which lies about halfway between Seville and Cadiz, and close to the town of Puerto Santa Maria, which was attacked by cholera, escaped also from the disease. This town possesses a very excellent water-supply, brought down some few years ago from a spring in the mountains by a native Company, at a cost of 300,000*l*.

Malaga has a population of 115,882. This city is in even a worse sanitary condition than Seville as regards its drainage, and a great deal worse as regards its cleanliness. In the old portion of the town the streets are narrow, unventilated, and intolerably filthy; the climate in summer is almost tropical.

It is difficult to obtain reliable data as to the cases of cholera in Malaga, as attempts were made to prove that no real cholera existed in Malaga; but there can be no doubt that from June to September the cholera did exist, and it is probable that during the whole of the summer there occurred some 200 or 300 real cases of Asiatic cholera. But the disease never became epidemic, although to all appearances the city offered a most excellent medium for the propagation of the disease, and on all former visitations had suffered very severely. But Malaga during the last few years has been provided with an excellent water-supply drawn from some springs situated at Torremolinos, on the coast to the westward of the city, and piped from thence into the city; and although the precautions adopted were not so complete as those at Seville, yet a more or less successful attempt was made to prevent the use of any other water than that brought from Torremolinos.

We have now examined the case of the few towns in Spain that possess a pure supply of water drawn from springs not liable to any specific contamination, and we have seen that, in all cases where such a supply existed, the cholera, although present in all of them, never made any headway or became truly epidemic, although in every case, except that of Madrid, there was no proper drainage, and the sanitary conditions were in many cases as bad as they could be.

Let us now look on the other side of the picture. We will commence with Granada—population 76,005. As regards its sanitary arrangements this city is on a par with Malaga; about one-tenth of the town is drained, but the sewers are of a very inferior class. The city is supplied with water by canals derived from the Genil and Darro, the two rivers which serve to irrigate the magnificent plain which spreads round it. A small portion is supplied from a spring called La Fuente Grande de Alfacar. The canals are uncovered, and are exposed to all kinds of contamination.

Through the streets the water is conducted in earthenware pipes, after the style of the Moors; many of the pipes are the original ones put down by these people before the conquest of the city by Ferdinand and Isabella. The cholera broke out about the middle of July. It is supposed to have first been brought in by some labourers who had arrived from Murcia, where the cholera was raging. It spread with frightful rapidity, and by the middle of August the official number of cases reported was over 450 per day. It died out, or rather wore itself out, about the middle of September. The total official returns give a total of 6471 cases and 5093 deaths, but in the city itself these returns are said to be much under-estimated; some, indeed, say the numbers should be doubled.

No attempt was made, as was done at Toledo with such excellent results, to suppress the old water-supply, and the epidemic took in a short time such alarming proportions that the local authorities were completely paralysed. It was difficult to carry on the interment of the bodies, and at one time from 400 to 500 corpses were lying piled up in the cemetery, awaiting interment.

The course of the cholera may be followed down the Rivers Darro and Genil, the infected waters carrying death wherever they were used for drinking-purposes.

Murcia—population 91,805—from which the cholera was imported into Granada, suffered heavily also. It was carried into the plains of Murcia by the waters of the River Segura from the baths of Archena, and it was imported into Archena by some invalid soldiers who were sent to the baths from the infected district round Valencia. The plain of Murcia is irrigated by the waters of the Segura, and the disease commenced in this district with the death of a labourer who had drunk the water of one of the irrigation channels. The inhabitants of Murcia and of the plain use principally water from the irrigation canals or from the river; this water is usually stored in large jars similar to those

which held Ali Baba and his forty thieves, and amongst well-to-do people it is customary to keep a year's supply in hand; that is to say, the water is allowed to repose for one year before use in a reservoir or "algibe," constructed on purpose, or in some of these large jars sunk up to their necks in the ground; by this means it becomes perfectly clear, cool, and palatable. The poorer classes are, as a matter of course, not able to take these precautions, and have to drink the water from the canals, or after a few days' repose only.

The epidemic raged principally amongst the little cottages scattered thickly over the plain or garden, as it is called, but the disease never developed itself in Murcia as it did in Granada, and the city itself escaped better than might have been expected. May this not be attributed to the fact that the greater part of the people in the city were drinking water collected in the foregoing year, before the cholera had appeared on the sources of their water-supply? And if this be so, may we not anticipate a fresh outbreak this year, if the choleraic poison or germs are capable of outliving a year's repose and darkness?

In reference to water-supply and cholera, no case is so instructive as that of Valencia. This city is fairly well drained, as drainage goes in Spain, and as regards cleanliness is certainly in a better situation than Malaga or Granada. The water-supply is derived from the River Turia; it is taken from the river near the town of Manises, about three miles and a half above Valencia; it is passed through sand filters situated between Manises and Mislata, and is stored in a covered reservoir, from whence it is conducted by iron pipes, a distance of about one mile and a half into the city.

In one of the interesting letters written by the special correspondent of the *Times* during his tour of inspection of the cholera districts, a very clear description is given of the track taken by the cholera from its starting-point in Alicante, where it had broken out at the latter end of 1884, to Valencia in 1885. During the course of the year 1884 the disease had crossed the frontier of the provinces of Alicante and Valencia, and established itself at Jativa, a somewhat important town, situated on one of the affluents of the Jucar—this and the Turia being the two rivers whose waters are used for the irrigation of the wonderful "Huerta," or Garden of Valencia. During the winter the disease lay dormant, but it broke out in the spring of 1885, and travelled rapidly down the river to Alcira, attacking the various towns situated on the river itself, or on the canals derived from it.

The epidemic was severe at Alcira, but, as the *Times* correspondent suggestively remarked, it ceased so soon as the inhabitants gave up drinking the river-water, and took their supply from a spring situated at a considerable distance from the town. From Alcira it travelled across the network of canals till it reached the river Turia. The *Times* correspondent says:—"It came very near Valencia, and yet never touched the capital till it had worked right round."

At last, in the middle of May, having crossed the water-supply of the city and thoroughly infected the river, it attacked the city right royally, and by the end of June the number of cases had risen to 700 daily, out of a population of 143,861. The disease died out in September, having, according to the official accounts, attacked during the four months 4234 people.

We will now turn to Saragossa. Saragossa, the capital of the ancient kingdom of Aragon, is situated on the right bank of the River Ebro; it contains 84,575 inhabitants, and is an important city. Like most Spanish towns and cities it has no sewers: fœcal matter is collected, as in Seville, in cesspools, which are periodically emptied.

Its principal water-supply is derived from the Canal de Aragon, which in its turn draws its supply from the Ebro, near Tudela. This canal was intended principally for navigation, and is now used for this purpose, and also for irrigation. It passes at a short distance above Saragossa, and the town supply, after being drawn from the canal, is stored in reservoirs, and, after depositing its mud, is then passed through charcoal filters. Some of the inhabitants of the city drank the water from an irrigation canal taken from the River Jalon; some used the waters of the Ebro, which flows close past the old walls of the city.

The disease broke out in Saragossa shortly after the middle of July, and the number of cases during the time the epidemic raged was close upon 10,000. The proportion of deaths was small, thanks to the heroic and energetic conduct of the authorities and the people. Some time before the commencement of the disease in the city a number of small towns on the banks of the Ebro and the Jalon had been attacked by the cholera; there was therefore ample opportunity for the infection of the water-supply. Against such contamination the only protective measure as regards the general supply was the filtration through charcoal; as regards the Jalon water, there was no protection. This source of supply was, however, ultimately stopped by the authorities, who prevented the water reaching the city, with a notable result as regarded the decrease of the epidemic in the quarter served by them.

It would be interesting to follow out still further the line of inquiry I have adopted, but the examination would be too prolix for the present purpose. The cases I have presented are typical ones; they might be increased *ad libitum*, but I think they are sufficient for my purpose. From an examination of them it would appear as though, in the case of cholera, drainage and sewerage is a secondary subject, the primary one being the water-supply. We have seen that the cities of Toledo, Seville, and Malaga, although in bad conditions as regards their sewerage and general sanitary arrangements, yet escaped from any serious attack of cholera, whilst Murcia, Valencia, and Saragossa suffered most severely, although in their case the sanitary arrangements were certainly not worse, but if anything better, than the three former cities. But, in the case of the three first-named cities, each one enjoyed a supply of water drawn from springs situated at a distance from the city, and carefully watched and guarded to prevent any contamination, and the exclusive use of this water was rendered imperative by the authorities.

In the case of Valencia, Saragossa, and Murcia we have a supply drawn from rivers subject to contamination from various sources, against which the only protection was that furnished by the doubtful process of filtration.

There can be no doubt that the cholera attacks in preference those who live under unsanitary conditions, and whose habit of body is by this means prepared to receive the germs of any disease that may be prevalent.

There is no doubt that the virus can be conveyed about from one place to another, like small-pox, typhus, and various other diseases, either by clothes or in the human body, and where it finds a proper medium it will develop itself and extend; but, like these other diseases, it can in these conditions be isolated, fought, and conquered, but without doubt the medium *par excellence* for the spread of cholera-poison is water, and more particularly so when water so infected is used for dietetic purposes.

When it gets possession of the water-supply of a city, no bounds can restrain it; there is but one resource, and that is the cutting off of the water.

We do not yet know in what the choleraic poison consists; it is in all probability a micro-organism of some sort which is capable of very rapid development in water, but it cannot be yet said what is the particular micro-organism which produces cholera. The "comma Bacillus" of Koch has not been accepted by the scientific authorities; on the contrary, very high ones deny

altogether its identity with cholera, and assert that it is to be found in the mouth of every healthy person. Whatever the specific germ may be, it is at least doubtful whether any filtration will intercept it; from the experience obtained at Valencia and Saragossa it appears evident that neither sand nor charcoal will do so.

In a paper read recently at the Institute of Civil Engineers, Dr. Percy Frankland asserts that the London Water Companies do, at the present moment, eliminate 96 per cent. of all the micro-organisms in the Thames water by simple filtration through 3 feet of fine sand. This may be so, but it is equally certain that filtration through sand, even at a very slow speed indeed, will not eliminate the minute particles suspended in waters of a deltaic character, and which gives such waters their peculiar colour. If sand is incapable of intercepting these particles, it may also be incapable of intercepting the specific germs or poison that produce cholera in the human body.

Filtration is, at the best, but a doubtful proceeding for the purification of water. It is impossible to control effectually the speed of the filters; they vary at every moment, and although a mean term may be arrived at by taking the area of the filter-beds and the volume of water filtered in the twenty-four hours, yet this really affords no reliable guide as to the actual speed at which the water has passed the filters. It is probable—nay, almost certain that, out of a given quantity of water, no two gallons have passed at the same speed, and it is possible and probable that one-half of the total volume may have passed the filter at double or treble the speed of the rest.

To insure immunity from contamination, the only real and practical method appears to be that of capturing the water at a pure source and conducting and delivering it in such a way as to render it impossible that any specific germ or poison should have obtained access to it. In the matter of cholera, for instance, with the experience of Valencia and Saragossa before us, one cannot feel any confidence in water which is taken from a river liable to so many sources of contamination as is the Thames, and it is at least doubtful whether any system of filtration would be capable of eliminating cholera-poison from such waters. It is extremely probable that simple filtration through sand will not do it.

The very interesting series of letters published by the *Times* on the subject of cholera in Spain afford much valuable data as to the causes of the disease, or rather as to its mode of propagation. It is unfortunate that the writer seems to have gone out with a preconceived idea that the cause of the propagation of cholera was defective drainage, and consequently to have devoted the greater part of his time to the examination of the sewerage of the various towns he visited, and of their general sanitary arrangements, the water-supply being as a rule relegated to the second place. He appears to be a strong advocate for traps, and not to be aware that the best sanitary authorities of the present day are beginning to doubt very strongly the utility of traps, and to rest their practice rather on the thorough ventilation of sewers, the rapid discharge of their contents, and a complete disconnection between the house drainage and the main sewers.

It is not too late for some scientific investigator to go over the track of the cholera invasion in Spain, to trace the progress of the disease in the towns it visited, and ascertain all the facts connected with their drainage and water-supply, and also, what is not less important, examine the conditions of those towns which so far have enjoyed a practical immunity from the epidemic. As much is to be learned from this negative evidence as from the other.

Pending the discovery by scientific men as to the particular germ or poison that creates cholera, such a practical examination as I suggest would be of immense value to us, by teaching how the propagation of the disease is principally brought about, and what are the best means of preventing it.

GEORGE HIGGIN

NOTES

THE Royal Society *conversazione*, on June 9, was in all respects satisfactory. We can only afford to refer briefly to a few of the exhibits which attracted the interest of the numerous visitors, who were received by Professor and Mrs. Stokes. A room was devoted to telephones connected with the Savoy Theatre, and the company were delighted to hear the Mikado under such novel conditions. The models of the Romano-British village near Rushmore, on the borders of Dorset and Wilts, between Salisbury and Blandford, exhibited by Lieut.-Gen. A. Pitt-Rivers, F.R.S., attracted much attention. The rare earths from samarskite, gadolinite, &c., with illustrations of their phosphorescent spectra, exhibited by Mr. W. Crookes, F.R.S., were magnificent. The pumice, volcanic ash, drawings, diagrams, &c., illustrative of the effects produced by the great eruption of the island of Krakatão, Java, in August 1883, exhibited by the Krakatão Committee of the Royal Society, proved very attractive, as did the fine collection of astronomical photographs exhibited by Mr. Common, Dr. Gill, the Solar Physics Committee, and others. At 9.30 and 10.30 the stellar and solar photographs were demonstrated, and at 10 Mr. Common demonstrated the photographs of nebulæ and comets. The first series included the stellar photographs recently taken by the Brothers Henry at the Paris Observatory. The remaining photographs had reference to solar phenomena, and consisted of two series, one from Meudon, the other from Kensington; the former, contributed by Dr. Janssen, had reference to the minute portion of the solar surface; the latter, to some recent attempts to photograph the spectra of sunspots and prominences. The photographs of planets, comets, and nebulæ, exhibited by Mr. A. A. Common, F.R.S., consisted of (1) series of photographs of Saturn; (2) series of photographs of Jupiter; (3) photograph of Mars; (4) nucleus of the great comet 1882; (5) the Dumb-bell Nebula; (6) the Crab Nebula; (7) the Spiral Nebula; (8) the Great Nebula in Andromeda; (9) series of photographs of the Great Nebula in Orion, with exposures of 1 min. to 80 min. (the above were all taken with the 3-foot reflector at Ealing); (10) recent photographs of Saturn, Jupiter, and the nebulæ in the Pleiades, by the Brothers Henry.

AT the annual meeting of the American Academy on May 25, it was voted to present the Rumford gold and silver medal to Prof. Langley, of the Alleghany Observatory, for his researches on radiant energy.

THE thirteenth annual meeting of Scandinavian naturalists will take place in Christiania between July 7 and 12.

WHILE Mount Etna has again quieted down during the past week, volcanic energy has manifested itself at the Antipodes in an unexpected quarter. Though the North Island of New Zealand is known to be greatly volcanic, and has in Tongariro an active volcano, there has been no destructive eruption within the memory of man. The eruption therefore telegraphed on June 10 was quite unexpected. It occurred in the Tarawera district, on the east side of the Tarawera Lake, lying in a line between the Bay of Plenty and the mouth of the Wanganui River. It is a long way north from Tongariro, and in the midst of the wonderland of Rotomahana's hot springs and many-coloured terraces. The country is stated to be in a disturbed state for many miles around, and it is estimated that a hundred natives and ten Europeans have perished.

A SHOCK of earthquake was felt on Friday night at Sandy Hook and Coney Island, New York, U.S.

AN earthquake was felt at Bougie, Algeria, on June 10; no accidents are recorded. On the same day a heavy thunderstorm raged in the vicinity of Versailles. The lightning struck a tent at Sautenay camp; sixty soldiers were lying under it; many were hurt, but none killed.

ARRANGEMENTS are in progress for the establishment of an aquarium and winter garden in Stockholm.

DURING the present summer a university will be opened at Tomsk, in Siberia, the first of its kind in this part of the Russian Empire. At first it will consist of two faculties—a historical-philological one and a physical-mathematic. It already possesses a library with 50,000 books, a very valuable palæontological collection, presented by Duke Nicolaus of Leuchtenberg.

EARLY last year the East Indian section of the Dutch Royal Institution of Engineers published some prize questions for essays. One of these subjects was the theoretical methods and calculations used when making deductions from observations on earthquakes, together with positive data as to the situation of the point of egress of a given shock. The first prize of 150 guilders and a diploma was awarded to Prof. Milne of Japan. He also received honourable mention for an essay on another question respecting the application of the theoretical principles of seismological science to the art of house-building, especially in the Netherlands Indies, the prize committee at the same time asking for permission to use his observations and suggestions in a work under preparation by one of the members of the committee, who has studied Javanese seismological phenomena and Javanese methods of architecture.

IN a paper in the last number of the *Journal* of the American Oriental Society Dr. Martin, the head of the Foreign College at Pekin, writes on the "Northern Barbarians" of Ancient China, or the tribes which harassed the northern frontier. The ethnology of these and other tribes inhabiting China and the adjacent regions is at present engaging much attention from Oriental scholars, and especially in England that of Prof. de Lacouperie. Dr. Martin confesses that we are still in darkness respecting the ethnology of these northern tribes. Even in regard to the great tribe of Hiongnu, which is conspicuous in history for many centuries about the commencement of the Christian era, it has been much disputed whether they were Turks, Huns, or Mongols. Dr. Martin thinks that these tribes of prehistoric times were probably not inferior to the Chinese in form, feature, or natural intelligence, as their descendants, the Manchus and Mongols, are not inferior in any of these respects. In reply to the question were they originally of one mould, or have the lines of distinction become gradually effaced by the intercourse of ages, he thinks the latter the correct hypothesis. He believes that the primitive Chinese type, that imported by the immigrants who founded the civilisation of China, is no longer to be discerned. In the southern and central regions it has everywhere been modified by combination with the aboriginal inhabitants, leading to provincial characteristics, which the practised eye can easily recognise. It has probably undergone a similar modification in the northern belt, where it met with tribes akin to those of Mongolia, and gradually absorbed them. This process was going on in prehistoric times; history at its earliest dawn shows us the unassimilated fragments of these tribes, and at the same time discloses a vast movement southward all along the line. In the historic period these tribes, organised into great states, established in China a dominion enduring for centuries. They have, Dr. Martin thinks, stamped their impress on the people of this region as thoroughly as the Saxons have theirs on the people of England, or the Vandals theirs in that part of Spain which still bears their name in the form of Andalusia. In their turn the invaders have been subjected, in all ages, to influences under which they exchanged barbarism for such civilisation as they found among the more cultivated race.

THE assertion that from the top of the Eiffel tower communication could be established with Dijon, a place situated 304 kilometres from Paris, is not quite correct. The altitude of this proposed monument being only 300 metres, the radius of the horizon could not exceed 80 kilometres, if we disregard the inequalities of the surface. But the mountains which separate the basin of the Seine and that of the Rhone, which are in Côte d'Or, although not very lofty, may possibly be perceived from an elevation of 300 metres at Paris, under the most favourable circumstances, and they are not very far from Dijon. Practically such a tower could be used for placing Paris in communication with any army occupying these mountains. These facts are sufficiently proved by the success of the great triangulation executed by Col. Perrier between the province of Oran and the Sierra Nevada at a distance of over 200 kilometres. The question is, if it is possible to erect this structure, whether it is worth the money required to build it, and whether the effect will not be to destroy all harmony in the great Exhibition. This question is not settled yet.

WITH reference to Mr. Caldwell's observations in which he found that Monotremes are oviparous with mesoblastic ovum, a correspondent sends us the following quotation from a work by Robert and Thomas Swinburn Carr, entitled "The Literary Pancratium," foot-note on p. 8 (London, 1832).—"But this is New Holland, where it is summer with us when it is winter in Europe, and *vice versâ*; where the barometer rises before bad weather, and falls before good; where the north is the hot wind, and the south the cold; where the humblest house is fitted up with cedar; where the fields are fenced with mahogany, and myrtle-trees are burnt for fire-wood; where the *swans are black* and the eagles white; where the kangaroo, an animal between the squirrel and the deer, has five claws on its fore-paws, and three talons on its hind-legs, like a bird, and yet hops on its tail; where the mole lays eggs, and has a duck's bill; where there is a bird with a broom in its mouth instead of a tongue; where there is a fish one half belonging to the genus *Raja* and the other to that of *Squalus*; where the pears are made of wood, with the stalk at the broader end; and where the cherry grows with the stone on the outside.—Field's *New South Wales*, p. 461."

JUST as improved machinery, adopted in a locality to which the old trade was a stranger, through not being there hampered with old customs and much invested capital, may bring with it the future trade, so an intelligent and rapidly-progressing nation like Japan, by the free choice of the latest improvements in educational organisation from both Europe and America, may even have something to teach. Hence the United States Bureau of Education has lately published a circular containing a statistical survey of the system now adopted there. There is a Minister of Education over all; candidates for school committees are nominated by each locality—either a large city or a province—into which the country is divided; a selection is made from them by the Governor, and the chosen members are paid. There are schools of general education divided into three grades, to pass through all of which occupies eight years. The study of literature gives the choice of either Japanese or Chinese, the former requiring three years, the latter four. English, or if preferred, French or German, is required to be learnt in all middle-class schools, as well as in the highest. At the one University a course of instruction in the department of science is provided in mathematics, physics, chemistry, biology, astronomy, engineering, geology, mining, and metallurgy. There are astronomical and meteorological observatories, botanical gardens, and museums. Courses are provided in medicine, leading up to a special degree after a course of five years, and in

pharmacy after a course of three. Independent of the University are the Military Academy and the Engineering College, the last two out of the six years' course of the latter being spent in practical applications. Technical education is divided into chemical and mechanical There are higher schools in the country for nearly every special purpose; but with all this carefully-proportioned system the titles and objects of thirty societies show how thoroughly the English system of voluntary association is making its way as a method of supply to educational demand.

On presenting to the St. Petersburg Academy of Sciences his new researches into the language of his "Codex Comanicus," published by Count Kunn, Prof. Radloff made a few remarks well worthy of attention (*Bulletin*, vol. xxxi. No. 1). After having carefully catalogued all words appearing in the "Codex," Prof. Radloff has collected, under each separate word, the words akin to it in different Turkish dialets, so as to show their kinship at once. It appears that the Comanic dialect belongs to the great group of Turkish dialects which M. Radloff describes as the Kypchak group; the parent language having been spoken from the ninth to the thirteenth centuries by those Tartars who inhabited the Steppes from the Altai Mountains to the Black Sea. They now comprise the Abakan Tartars, the Barabintsys, the Irtysh and Kazan Tartars, and the Kirghizes. The "Codex" thus offers a sample of the oldest language spoken by the Kypchak stem After having concluded his researches into this dialect, Prof. Radloff will devote his attention to the Uigur languages, for which we have so rich a material; and then he will take up the third group of the Seldjuck languages. Only after such an inquiry, he says, may we hope to attain a thorough knowledge of the whole of the Turkish languages, because all the newer material, and much of the older, belongs to the artificial written languages. The Osman and the Jagatai (or East Turkish) dialects are not representatives of defined groups of dialects, but artificial languages based, the latter on the Uigur language, and the former on the Seljuk, with a mixture of different other dialects. As to the Kazan written language, it is a most varied mixture, in which Osman are mingled with Djagatai forms, while the people are acquainted with neither of them.

We have received the *Proceedings* of the Windsor and Eton Scientific Society for the past year. It contains reports of a few lectures on general scientific subjects. We do not see any evidence of that local scientific work for which these societies are so remarkable, and which is the most beneficial outcome of their activity. Still, the President, who must be a good judge, in his address for the year states that the Society is steadily but surely making its mark as one of the many aids to intellectual improvement which are offered to the people of Windsor and the neighbourhood by the Albert Institute and the various societies associated with it.

Comment was made in this journal on a recent date respecting the enemies of frogs. Mr. W. August Carter, of the Fisheries Section of the Colonial and Indian Exhibition, has made further observations upon the subject, and finds that the tortoise must be added to the list of foes. With a view of substantiating this fact Mr. Carter placed some medium-sized frogs with several tortoises of the same dimensions, when the latter immediately attacked them ferociously, and held them firmly by the legs, notwithstanding their efforts to escape. The tortoises were, however, unable to devour more than a portion of the leg, which they did with much apparent difficulty, the frogs afterwards escaping, but only to be recaptured and similarly treated. Considering the tortoises measured only 1¼ inches in length, they displayed remarkable courage, whilst their agility was certainly greater than that usually displayed by these members of the Chelonian family.

A very large specimen of the Ascension turtle died at the Colonial and Indian Aquarium last week. It was the only one of this species on view, and had been the object of considerable notice on account of its colossal proportions. As a further proof of the tenacity of life amongst turtles, it may be remarked that this particular specimen had existed more than two months without food. At its death 100 eggs were found in it, the retention of which doubtless proved fatal to the turtle.

The additions to the Zoological Society's Gardens during the past week include an Ourang-Outang (*Simia satyrus* ♀) from Borneo, presented by Mr. H. H. Riccard; a White-handed Gibbon (*Hylobates lar*) from the Malay Peninsula, a Binturong (*Arctictis binturong* ♂), a White-whiskered Paradoxure (*Paradoxurus leucomystax*) from Malacca, presented by Mr. Dudley Hervey; a Binturong (*Arctictis binturong*) from Malacca, presented by Capt. Robert Hay; a Common Genet (*Genetta vulgaris*), South European, presented by Mr. J. Church Dixon; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Miss Grace Balfour; a Green Monkey (*Cercopithecus callitrichus* ♂) from West Africa, presented by Mr. Duncan Armstrong; an Indian Civet (*Viverricula malaccensis* ♂) from India, presented by Capt. Archibald Douglas, R.N.; a Herring Gull (*Larus argentatus*), British, presented by Mr. C. A. Marriott; two Black-billed Tree Ducks (*Dendrocygna arborea*), a Violaceous Night Heron (*Nycticorax violaceus*), a Brazilian Cormorant (*Phalacrocorax brasilianus*), a Fugitive Snake (*Dromicus fugitivus*) from the Bahamas, presented by Mrs. E. Blake; two Mexican Guans (*Penelope purpurascens*) from Mexico, presented by Mr. E. A. Clowes; a Garden's Night Heron (*Nycticorax gardeni*) from St. Kitts, West Indies, presented by Dr. A. Boon, F.R.C.S.; seven Common Vipers (*Vipera berus*), from Hampshire, presented by Mr. Walter Blaker; four Three-toed Sand Skinks (*Seps tridactylus*), South European, presented by Mr. J. C. Warbury; a Puma (*Felis concolor*) from South America, a White-handed Gibbon (*Hylobates lar*) from the Malay Peninsula, ten Adorned Ceratophrys (*Ceratophrys ornata*) from Buenos Ayres, deposited; two Viscachas (*Lagostomus trichodactylus* ♀ ♀), two Crossed Vipers (*Craspedocephalus alternatus*) from Buenos Ayres, a South American Flamingo (*Phœnicopterus ignipalliatus*), a Roseate Spoonbill (*Platalea ajaja*) from South America, a Harnessed Antelope (*Tragelaphus scriptus*), two Balearic Cranes (*Balearica pavonina*) from West Africa, two Lineated Kaleeges (*Euplocamus lineatus* ♂ ♀) from Tenasserim, a Porose Crocodile (*Crocodilus porosus*) from Ceylon, a Bald Ouakari (*Brachyurus calvus* ♂) from Brazil, purchased; a Burrhel Wild Sheep (*Ovis burrhel*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

The Melbourne Observatory.—We have received Mr. Ellery's Report, dated October 6, 1885, which refers to the year ending the previous June 30. The great reflector, after some slight repairs, readjustments, &c., is stated to be in excellent working order. The work done with this instrument has been chiefly confined to a revision of southern nebulæ, already observed by former observers, preliminary to publication. One hundred and seventy-two nebulæ have been re-observed and re-drawn to compare with the plates to be published. Many of these nebulæ have been observed twice, and some three times, and none were completed until they had been observed on a first-class night. The new transit-circle with object-glass of 8 inches aperture, constructed by Messrs. Troughton and Simms, has been in continuous use for all the meridian work of the Observatory since August 22, 1884, and has proved very satisfactory in every respect. The number of right ascension observations obtained with this instrument since its erection was 2287, and the number of declination observations 983, comprising observations of a list of stars selected by Dr. Auwers for reduction of zone and Transit of Venus observations, stars observed with comets, and stars selected from the Melbourne zones. All the individual observations are completely

reduced. The second Melbourne general catalogue, containing the meridian results from 1871 to 1884 inclusive, thus incorporating the whole of the results obtained with the old transit-circle up to the date of its disuse, is in process of formation. An alteration has been made in the photo-heliograph, so as to secure a picture of 8 inches diameter instead of 4 inches, as formerly. There have been several interruptions to the continuity of the sun-photographs during the year, owing to derangement of the instrument and dome, and only 130 pictures were obtained up to June 11, when the instrument was dismantled for repairs. The sixth volume of the results of astronomical observations for the years 1876 to 1880 inclusive, was published in February 1885, and has been distributed. The first part of the observations with the great Melbourne telescope (NATURE, vol. xxxiii. p. 538), from its erection in 1869 to the present date, has also been published during the year to which this Report refers.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *JUNE* 20–26

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 20

Sun rises, 3h. 44m.; souths, 12h. 1m. 14·5s.; sets, 20h. 18m.; decl. on meridian, 23° 27′ N.: Sidereal Time at Sunset, 14h. 14m.

Moon (four days after Full) rises, 22h. 7m.*; souths, 2h. 49m.; sets, 7h. 36m.; decl. on meridian, 15° 34′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	4 17	12 45	21 13	24 57 N.
Venus	1 50	9 14	16 38	15 14 N.
Mars	11 28	17 45	0 2*	2 41 N.
Jupiter	11 40	17 56	0 12*	2 19 N.
Saturn	4 40	12 50	21 0	22 37 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich)

M signifies maximum; *m* minimum.

GEOGRAPHICAL NOTES

THE paper on the aborigines of Formosa, by Mr. G. Taylor, in the *China Review*, to which we have already adverted, is continued in the last number (vol. xiv. No. 4), and as it progresses it contains more and more information, especially with regard to the number of different tribes and their various customs, which is wholly new, either in European publications or in those of the Far East. The number last noticed concluded with the Paiwans, the tribe with which the Dutch came in contact in the seventeenth century, during their temporary occupation of part of Formosa, and of which therefore we had the most information. The present instalment deals with several other tribes, including one very peculiar and hitherto unknown people, the Caviangans, who are comparatively few in number, inhabiting lofty mountains, and having many superstitions with regard to hills and the spirits which inhabit them. We have also an account of the Tipuns, the most powerful tribe in southern Formosa, inhabiting the great plain inland from the headland marked Double Peak on the charts of the east coast. These have a tradition that they came from some other country hundreds of years ago, but they appear now to differ little from their neighbours the Paiwans. But there is one very radical distinction, viz., that when a man marries he enters his wife's family, whereas amongst the Paiwans the reverse is the case. Amongst them tattooing is a mark of rank, and is strictly prohibited to the commonalty. Another tribe described is the Amias. The Chinese class these as aborigines, but the true aboriginal tribes look on them as foreigners. They have a curious tradition of their origin, but the aborigines have the more prosaic one of shipwreck, and it appears that the Amias do not consider themselves entitled to equal social rank with the other savages. In appearance and customs they differ much from their neighbours, and worship one Supreme Being, not a multitude of spirits. They believe in an after state, dependent on personal conduct in this life, and they have a sort of purgatory amongst their beliefs. They have a vague notion of lands and peoples where communication is carried on by means of other than oral speech. This, says Mr. Taylor, is the only trace in South Formosa of any original idea of writing. Their explanations of certain natural phenomena, such as thunder and lightning, sunset and sunrise, are curious. Earthquakes they believe to be caused by a pig scratching itself against an iron bar stuck into the earth. This paper leaves on the mind, even more strongly than its predecessor, the impression that in the future Formosa will offer ethnological problems as interesting and complicated as any equal area on the earth's surface. It is clear, too, that all the divisions of the inhabitants of the island hitherto given by writers, whether Chinese or Europeans, are wholly incorrect and unscientific. There are wider differences amongst the tribes, and a far greater number of different tribes, than has ever been supposed. Moreover, it is obvious that in the present state of our knowledge of the tribes, it would be idle to theorise about them. Mr. Taylor, dealing only with a very small section in the south of the island, has described six or seven tribes; amongst these we find some calling themselves aborigines, and looking down as strangers and new-comers on others who have been generally supposed to be aborigines. In view of the wild and inaccessible nature of a large part of the eastern half of Formosa, and of the danger of entering it on account of the chronic state of war which exists between the natives and their Chinese masters, it must be a long time before a clear or trustworthy ethnological account of Formosa can be written. It is quite possible that some of the largest ethnological problems of the Far East may be involved in Formosa; the knot may, perhaps, lie there. Meantime, Mr. Taylor deserves thanks for his careful and interesting collection of new facts which are vital to the discussion of Formosan ethnology.

A REPORT addressed by Col. Fontana, the Governor of Chubut, to the President of the Argentine Republic, gives details of the exploration of Chubut up to the Andes lately made by the Governor. The Expedition, consisting of thirty men, left Raiwon, the chief town of Chubut territory, on October 14, and returned on February 8, having traversed about 1000 leagues in four months. It first followed the tortuous course of the Rio Chubut to its source in the Cordilleras, about the 42nd degree south latitude, the northern limit of Chubut, and then, crossing well-watered and fertile prairies and enormous forests, reached the 46th parallel. It discovered three passages into Chili, and laid down accurately the courses of several rivers heretofore fixed by guess-work. Col. Fontana believes he was the first to quench his thirst in the spring from which the River Senger takes its rise: he has removed the doubts which existed respecting Lakes Colne and Musters, and verified their positions; and he has determined the geographical position of the spots at which the Senger and Chico debouch into the lake. He promises in a short time to have completed maps which will correct many errors concerning the hydrography and orography of this region.

We have received the annual report for 1885 of the Russian Geographical Society, which contains short accounts of the expeditions of M. Prjevalsky to Central Asia, M. Potanin to China, M. Grum-Grzimailo in the sub-Pamir region, MM. Wolter and Trusman; and the usual notices on works for which the medals of the Society were awarded. Geographers surely will be sorry not to find in this report any notice of the work done by the Caucasian and Siberian branches of the Society, which usually so greatly increases the value of the annual report of the Russian Geographical Society.

We are glad to learn from the last Annual Report of the Russian Geographical Society that the Appendix to the *Russian Gazetteer*, by P. P. Semenoff, is in course of preparation. The full edition of the observations at the Polar Stations on Novaya Zemlya and on the Lena; the remarkable collection of maps dealing with the delta of the Amu-daria, Baron Kaulbars; and a geological map of the shores of Lake Baikal, are also in preparation.

At the last meeting of the Paris Geographical Society, Dr. Maurel read a paper on his travels in Cochin China and Cambodia, on a mission from the Minister of Public Instruction. By means of a series of maps representing the Indo-Chinese peninsula in the seventh, eleventh, eighteenth, and nineteenth centuries, he showed the relative importance at different epochs of each of the peoples inhabiting this region. He then gave a general account of the country, its geography, climate, population, &c. A large collection of ethnographical objects which he had with him added much interest to that part of his paper. The young Cambodians at present being educated in Paris were present, clothed in the national costume.

THE DETERMINATION OF THE INDEX OF REFRACTION OF A FLUID BY MEANS OF THE MICROSCOPE

Of the various means adopted hitherto for the determination of the refractive index of a fluid, the most usually adopted has been that of the hollow prism, telescope, and collimator.

This method involves (α) the determination of the angle of the prism; (β) the position of minimum deviation; (γ) the use of monochromatic light, if errors arising from the different dispersive qualities of the substances are to be avoided. These preliminaries render the labour of determining the index a very difficult task, and the observer will scarcely expect to accomplish more than one observation at a sitting.

Cleaning the prism is not the least of the troubles, and when we add to them the fact that many liquids are so opaque that sufficient light can scarcely be passed through them for the observation, it is not surprising that so few have been found to possess the courage necessary for attacking the problem. The writer having had occasion for frequent determination of the index of refraction, has found the use of the microscope far surpasses the usual method in giving results of the greatest delicacy combined with a minimum of cost and of time.

Starting with the well-known fact, that an object viewed through a medium whose refractive index is different from that of air will occupy a different position from its image, or in the language of the text-books, $v = u + \frac{t}{\mu}$, where v determines the position of the geometrical focus of a pencil after direct refraction through a plate whose thickness is t, the writer was led to adopt the following plan.

On an ordinary "slip" as used for mounting preparations for the microscope a delicate mark is made with a writing diamond. A large but very thin "cover-glass" is cut in half, and its pieces cemented to the "slip" on either side of the mark, leaving a space of about one-eighth of an inch; then, resting on these supports, and bridging over the intervening space, is placed a small but very thin "cover-glass," and a drop of the fluid to be examined is run under this.

The fine mark made on the "slip" is now viewed through this with the microscope, using as high a power as possible, for the higher the objective the more delicate will be its focal adjustment; when the object is in focus the position of the "fine adjustment" must be read off. The microscope must then be left, and the slip removed for the examination of any other fluid. The top cover-glass is lifted off, the slip cleaned, the *same* cover-glass replaced, and a drop of a different fluid run under. Replacing now the slip upon the stage, and looking for the mark which was previously in focus, it will be found that an alteration of the fine adjustment is necessary to bring it into focus.

If the medium is of lower refractive index, the objective will have to be lowered, and conversely. Thus a rapid comparison of the relative refractive indexes of two media may easily be made.

But not only can the relative refractive powers of different bodies be thus obtained; the absolute numerical values may with the greatest accuracy be determined. For this it is essential that the fine adjustment screw should have accurate micrometer divisions, and this is usually the case now that immersion objectives are in common use. Two fluids must be selected whose refractive indexes present a wide difference, say oil of cassia and water; focus the mark, first viewed through water, secondly viewed through oil of cassia, and read off the number of divisions the screw has been turned through in the alteration of the focus. The refractive indexes of oil of cassia and water being known from the tables, a numerical value will by the formula be obtained for each division of the screw-head, and thus the absolute numerical index of any medium easily be determined.

By this simple and inexpensive method the writer has obtained from fifteen to twenty absolute indexes in a sitting of an hour's duration.

The importance of obtaining suitable media of high refractive index for mounting objects to be viewed with very high powers cannot be overestimated, for not only is a wider cone of light thus brought to bear upon the object, but its image is advanced, so that a greater working distance is obtained between the front lens of the objective and the cover-glass.

Gordon Thompson

St. Charles's College, Notting Hill

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

Cambridge.—The twentieth annual report of the Museums and Lecture-Rooms Syndicate, lately issued, recounts continuous progress in many scientific departments. The number of students attending demonstrations in the Cavendish Laboratory reached 100 last winter, and during the year twelve persons have done original work in the Laboratory.

The Plumian Professor (Mr. G. H. Darwin) introduced a new feature last summer by giving a course of lectures in the Long Vacation, and the attendance (thirteen) was encouraging. Few students attend the Plumian Professor's advanced lectures on the orbits and perturbations of planets.

In mechanism Prof. Stuart reports that the temporary museum and lecture-room has become very insufficient.

In chemistry there has been a considerable increase of students in advanced classes and special departments. The new laboratory is now being vigorously advanced. The classes in mineralogy maintain an average of sixteen students. The acquisition of 250 specimens from Mr. Field's collection has added some minerals previously unrepresented, and has improved the collection considerably for students' use.

In geology Prof. Hughes regrets the disadvantages of his present accommodation for teaching and lecturing, and finds the specimens of value are lost to the Museum because of its inadequate means of displaying them. A valuable collection of Cretaceous Cambridge fossils, many of them type-specimens, has been presented by Mr. James Carter of Cambridge.

Mr. Marr, Fellow of St. John's College, is engaged upon the arrangemext of the Foreign and British Cambrian fossils, of which it will be desirable soon to publish a new catalogue. The petrological series has been rearranged, and also the collection of microscope slides. The Upper Jurassic fossils have been largely added to and rearranged. Many interesting additions to the museum are chronicled in the report. It shows how largely the Museum gains from the interest of present and former students at Cambridge.

Prof. Babington has been chiefly occupied with the study of different parts of the Herbarium—especially the magnificent collection of European Rubi—and the identification of plants sent by botanists from a distance. Dr. Vines's students have numbered nearly sixty, and the Botanical Laboratory is inconveniently crowded. The commencement of a botanical museum has been made by Messrs. Potter and Gardiner, with the object

of illustrating the ordinary text books in the hands of students. Many interesting specimens have been given by Sir Joseph Hooker and Mr. Thiselton Dyer, Messrs. Potter, Vines, Gardiner, Hillhouse, and Miss B. K. Taylor of Girton College.

In the Museums of Zoology and Comparative Anatomy some most useful work has been done by the Strickland Curator (Mr. Gadow) in exhibiting the characteristic parts of birds, labelled and illustrated by printed descriptions. A lecture-room for animal morphology is urgently required. The attendances in the Lent Term this year were:—Elementary Biology, 163; Elementary Morphology, 94; Advanced Morphology, 16; total 273. Besides the two lecturers, nine graduates and advanced students took part in demonstrating to the classes. Prof. Macalister reports that the new iron dissecting-room has been very satisfactory, and far more anatomical work has been done than ever before in the University.

The number of students in the elementary physiology classes have averaged 130 each term; while an average of over 30 attended advanced lectures. In pathology Prof. Roy has given systematic lectures on general pathology, a demonstration course on morbid anatomy, a practical pathology course, morbid histology classes, &c., and has found it necessary to engage Mr. Joseph Griffiths, M.B. Edin., as his assistant. Space and other accommodation being deficient hampers the extension of the work.

Vigorous work in natural science will go on during July and August. Mr. Fenton will give a course of chemistry, and the University and Cavendish Laboratories will be open. Mr. Potter will lecture on systematic botany with practical work. Repetition classes in histology and physiology will be given by a demonstrator, and Dr. Hill will conduct a class for practical histology. Prof. Macalister will give demonstrations in osteology; and other lectures will be given regularly in connection with the medical school by Prof. Humphry, Prof. Roy, Dr. Anningson, Dr. Ingle, &c. The courses will begin from July 7 to 12.

Mr. W. H. Caldwell, Fellow of Caius College, and Balfour Student, having returned to Cambridge from Australia with a large supply of valuable material, asks for a room in which to prosecute his original researches. This it is proposed to supply at a cost of 110*l*. on the roof of a portion of the Museum Buildings.

SCIENTIFIC SERIALS

American Journal of Science, May.—The columnar structure in the igneous rocks on Orange Mountain, New Jersey, by Joseph P. Iddings. This paper, read before the Philosophical Society of Washington, June 1885, deals especially with the large vertical columnar formations of O'Rourke's Quarry south of Llewellyn Park, and with the still more interesting case of curving and radiating columns in the Undercliff Quarry near the north gate of the same park. These lava sheets are studied in connection with the general theory of columnar formation, which is attributed to a cracking produced by the shrinkage of the mass upon further cooling after it has consolidated into rock, which still retains a great amount of heat. As the consolidation due to surface-cooling proceeds inward, the resistance to contraction parallel to the surface increases at a greater rate than that normal to it, a point may then be reached where resistance in the first-named direction will exceed that in the second, and the resulting rupture will be *perpendicular* to the cooling surface. The wavy form of some of the columns in Orange Mountain suggests irregularities in the mass which disturbed the uniform advance of the lines of maximum strain, and caused them to deviate from parallelism.—Larval theory of the origin of tissue, by A. Hyatt. This is an abstract of a paper published in the *Proceedings* of the Boston Society of Natural History (1884), in which an attempt is made to trace a phyletic connection between Protozoa and Metazoa, and also to show that the tissue-cells of the latter are similar to asexual larvæ and related by their modes of development to Protozoa, just as larval forms among the Metazoa themselves are related to the ancestral adults of the different groups to which they belong. In the abstract the suggestion is added that Volvox and Eudorina are true intermediate forms entitled to be called Mesozoa or Blastrea. The author's conclusions bear directly on the results already obtained by Semper, Dohrn, and others in tracing the origin of the vertebrates to some worm-like type.—Cretaceous metamorphic rocks of California, by George F. Becker. During a recent investigation of the Californian quicksilver deposits by the United States Geological Survey, the crystalline and serpentinoid metamorphic rocks of the coast-ranges have been subjected to an elaborate examination. Pending a complete report, a summary of the results is given in the present paper, all detailed proofs being deferred until final publication. The field-work was carried out by the author and Mr. H. W. Turner, the chemical analyses by Dr. W. H. Melville; and the microscopical examinations jointly by the author and Mr. Waldemar Lindgren. The question of metamorphism has perhaps never before been studied under more favourable conditions: a solid basis has been obtained for further inquiry, while the results already secured are sufficiently definite to form an important aid for the investigation of metamorphic areas in other geological regions. One important result is the full confirmation of von Rath and Bischof's views regarding the probable conversion of feldspar into serpentine. There seems to be no doubt that the phenomenon occurs in the Californian coast-ranges where the feldspars are corroded externally, cracks widened irregularly and filled with serpentine, and in some cases elongated teeth of serpentine may be seen biting into the clear feldspathic mass. It is impossible to explain these and many similar occurrences, except on the supposition that a reaction between some fluid and the feldspars has yielded serpentine. Quartz also, which is well known to be sometimes converted into talc, is in the same region transformed into serpentine.—Arnold Guyot, by James D. Dana. This is a biographical sketch of the distinguished Swiss naturalist, brought down to the year 1848, when he settled in the United States.—On the determination of fossil dicotyledonous leaves, by Lester F. Ward. The writer offers some critical remarks on the views, and especially on the system of nomenclature, advocated by Dr. A. G. Nathorst of Stockholm in a paper on fossil floras recently published by him in the *Botanisches Centralblatt* (xxvi., 1886).—Pseudomorphs of limonite after pyrite, by Erastus G. Smith. It is shown that the common hydrated oxides of iron generally referred to limonite are undoubtedly alteration products of ferrous oxide, or decomposition-products of other iron-bearing minerals. Their secondary nature is clearly shown in the various occurrences where crystalline form is yet retained, giving clearly-defined pseudomorphs of ferric hydrate after the original mineral. An interesting case is described of such an alteration of pyrite into ferric hydrate, in which the crystalline form of the pyrite is sharply defined.—Influence of motion of the medium on the velocity of light, by Albert A. Michelson and Edward W. Morley. A series of important investigations are described, tending fully to confirm Fizeau's classical experiment of 1851, which proved that the luminiferous ether is entirely unaffected by the motion of the matter which it permeates.—Note on the structure of tempered steel, by C. Barus and V. Strouhal. The results are given of some experiments on the structure of steel, a full report on which will appear in *Bulletin* No. 35 of the U.S. Geological Survey.—Brookite from Magnet Cove, Arkansas, by Samuel L. Penfield. A description is given of a fine crystal of brookite from the collection of Prof. G. J. Brush. It belongs to the variety classed as arkansite by C. A. Shephard.

Bulletin de l'Académie Royale de Belgique, March 6.—Determination of the direction and velocity of the motion of the solar system through space, by M. P. Ubaghs. So far from being a constant quantity, the systematic aberration of the sun and its satellites was already shown to vary with time in right ascension and declination. It was also seen that, by taking into account this fact in studying the motion of the solar system, it might be possible to determine not only the direction and velocity of the motion, but also its extent and even the mean distance of the stars selected for the purpose of comparison. The author here undertakes to apply the principle to certain groups of stars of like magnitude, and although the results are not absolutely uniform, the agreement is sufficiently close to justify the conclusion that theory and practice are, on the whole, in harmony. The direction of the motion has been somewhat accurately determined, but the mean velocity expressed by the fraction 0·109 of the mean radius of the earth's orbit would appear to be far less than that usually attributed by astronomers to the motion of the solar system.—On the study of "arithmetical events," by M. E. Cesàro. In explanation of the expression "arithmetical events," this young and profoundly original mathematician remarks that the systems with which he is here occupied are constituted by numbers taken at hap-hazard. When such a system happens to

enjoy a property capable of being stated in advance, it constitutes for him an event (*un événement*). By means of some extremely difficult and subtle analytical transformations he arrives at a very general and remarkable formula, by means of which he solves with the greatest ease a number of curious arithmetical problems, such as: "What probability is there that in any given division the most approximate quotient will be the quotient by default (*par défaut*)? What probability is there that, if an integer taken at hazard be divided by the sum of two other integers taken at hazard, the quotient by default will be an odd number?"—On the oxidation of hydrochloric acid under the influence of light, by M. Leo Backelandt. This paper deals with the phenomenon observed by the author, that concentrated pure hydrochloric acid exposed to the action of sunlight in a badly-stopped flask after some time turns yellow, and emits an odour of chlorine. The change is shown to be due to a process of oxidation, the atmospheric oxygen consuming the hydrogen of the hydrochloric acid and liberating the chlorine. Under analogous circumstances hydriodic acid acts in the same way, liberating its iodine.—Notes on the rocks of Kantavu Island, Fiji Archipelago, by M. A. Renard. The author deals mainly with the andesites of the port of Kantavu, where they assume a columnar disposition.—Examination of the objections made by M. Hirn against the kinetic theory of the gases, by M. R. Clausius. While admitting the general care and accuracy with which M. Hirn has conducted his extensive experiments, the author argues on theoretical grounds that they are in no way opposed to the now generally accepted kinetic theory.

Rendiconti del Reale Istituto Lombardo, April 15.—On the permanent magnetism of steel at various temperatures, by Dr. G. Poloni. In this paper, which is supplementary to the two memoirs published by the author in 1878 and 1882, several interesting experiments are described with a series of magnets subjected to the action of heat within the limits of 15° and 300° C.—Note on a new acid isomerous with aspartic acid, by Prof. G. Körner. The formula of this acid, which the author proposes to name α-iso-aspartic or α-amido-isosuccinic acid, is—

$$\begin{array}{l} CH_3 \\ | \\ C{-}CO_2H \\ \;\; {-}NH_2 \\ | \\ CO_2H. \end{array}$$

Rivista Scientifico-Industriale, April 15.—A new method of measuring the thermic expansion of solid bodies, by Prof. Filippo Artimini. The author describes an ingenious apparatus which he has constructed for the purpose of determining with sufficient accuracy the increase in the linear dimensions of solids, derived from the internal motion communicated to matter by thermic energy.

April 30-May 15.—On the real atomic heat of simple bodies in the mechanical theory of heat and the formulas relating to it, by Prof. Alessandro Sandrucci. In Hirn's "Mechanical Theory of Heat" the expression *real atomic heat* is applied to the product of the atomic weight a of a simple body by its absolute calorific capacity K, and it is shown that this quantity should be independent of temperature, and equal and constant for all existing simple bodies; but the deductions are established independently of any hypothesis on the nature of heat. Prof. Sandrucci now inquires whether, given a certain hypothesis on the nature of heat, and determining the physical concept of *real atomic heat* in said hypothesis, it might be possible to obtain general and numerical results equal, or very nearly equal, to those already found by Hirn.—On a new saponiferous plant, by Prof. G. Licopoli. To the *Saponaria officinalis*, the *Quillaja Saponaria*, and a few other plants of this class Prof. Licopoli now adds the *Enterolobium Timbouva*, Martius, which is widely diffused throughout South Brazil and Uruguay.

SOCIETIES AND ACADEMIES

London

Royal Society, May 20.—"On the Lifting Power of Electro-Magnets and the Magnetisation of Iron." By Shelford Bidwell, M.A.

If an electro-magnet be excited by a gradually increasing current, a limit is soon reached beyond which the ratio of increase of sustaining power to increase of current becomes rapidly smaller; and it has generally been assumed that this ratio continues to diminish indefinitely, so that an infinite current would not impart to a magnet much greater lifting power than that which it possesses when an approach to "saturation" is first indicated. Joule estimated that the attraction would never be as much as 200 lbs. per square inch of sectional area; and, much later, Rowland assigned 177 lbs. per square inch, or 12,420 grms. per square centimetre as the limit for iron of good quality.

Having reason to doubt these conclusions, the author made some experiments with an iron ring cut into two equal parts, each of which was surrounded by a coil containing nearly 1000 turns of insulated wire. When one-half of the ring was used as an electro-magnet, and the other half as an armature (no current being passed through its coil), the weight supported was with a current of 4·3 amperes 13,100 grms., and with 6·2 amperes 14,200 grms., per square centimetre of surface. The lifting power therefore exceeded that which had been previously considered the greatest possible; nor was there any indication that a limit was being approached. But it was of greater interest to observe the effects produced when *both* portions of the ring were brought under the influence of gradually increasing currents, the conditions then being nearly the same as in Rowland's experiments. It was found that when the magnetic force had reached 50 C.G.S. units, at which point the weight sustained was about 10,000 grms. per square centimetre, the falling off in the rate of increase of the lifting power was well marked. And it continued to diminish until the magnetic force was 250 units and the weight supported 14,000 grms. But from this point *the magnetising current and the weight that could be carried increased in exactly the same proportion*, and continued to do so until the magnetic force had been carried up to 585 units, when the experiment was stopped, the maximum weight supported having been 15,905 grms. per square centimetre, or 229·3 lbs. per square inch. Detailed results are given in the first and second columns of the table. A curve plotted with the magnetic forces as abscissæ, and the weights lifted as ordinates, becomes, when the magnetic force is greater than 240 units, a sensibly straight line inclined to the horizontal axis.

It occurred to the author that these results might be applied to the investigation of the changes of magnetisation which correspond to changes of magnetic force. For if W = the grms. weight supported per square centimetre, H = the magnetic force, and I = the magnetisation, then for the divided ring

$$Wg = 2\pi I^2 + HI;$$

and by giving to W and H the values found to correspond, it becomes possible to find corresponding values of H and I. These are contained in the first and third columns of the table. When H has exceeded about 200, the ratio of I to H no longer continues to diminish, and the curve expressing the relation between them apparently becomes a straight line. Were the experiment carried much further, a tendency to a limit would probably be indicated; but if there is one it must be considerably higher than it is generally believed to be.

If k denote the susceptibility, μ the permeability, and B the magnetic induction, then $I = kH$, $\mu = 1 + 4\pi k$, and $B = \mu H$. Hence the values of k, μ, and B corresponding to different values of H can be found, and are given in the table. The figures in the last two columns are of great interest. Rowland, in order to exhibit the results of his well-known experiments in the form of a curve which (as he believed) would be of finite dimensions, plotted the values of μ as ordinates against those of B as abscissæ. The curve of μ thus obtained, after reaching a maximum for $B = 5000$, fell rapidly and in an almost straight line towards the horizontal axis. Assuming that the line would continue to be straight until it actually met the axis, Rowland concluded that the maximum of magnetic induction was about 17,500 units.

Now the greatest magnetic force used in Rowland's experiments was only 64 C.G.S. units; the imaginary part of his curve, therefore, corresponds to values of H ranging from 64 to infinity. A part of this exceedingly wide gap is filled by the author's experiments, in which H reaches 585; and if the values of μ and B given in the table are plotted, the curve will be found (after a rapid descent) to *bend round* soon after the limit of Rowland's observations, ultimately becoming, when B = 19,800, almost parallel to the axis of B.

The generally-accepted ideas as to the limits of magnetisation and magnetic induction therefore need modification.

May 27.—"On the Relation between the Thickness and the Surface-tension of Liquid Films." By A. W. Reinold, M.A., F.R.S., Professor of Physics in the Royal Naval College, Greenwich, and A. W. Rücker, M.A., F.R.S.

Plateau, Lüdtge, and van der Mensbrugghe have investigated experimentally the relation between the thickness and surface-tension of thin films. None of these observers, however, have used films thin enough to show the black of the first order of Newton's colours. The authors have therefore made a careful comparison of the surface-tension of black films with that of coloured films, the thickness of which was from 10 to 100 times greater. The principle of the method is the same as that utilised in Lüdtge's experiments. The interiors of the films to be compared are connected, and the relation between their surface-tensions is deduced from measurements by which their curvature is determined. In the authors' experiments a cylindrical film was thus balanced against another, which, though sometimes cylindrical and sometimes spherical, was initially of the same curvature as itself. The necessity for this arrangement arises from the fact that the authors' previous observations have shown that a cylindrical film thins to the black of the first order more readily than one of any other form. The fact that small changes in the forms of cylindrical and spherical films, attached to two circular rings, convert them into unduloids or nodoids, renders the mathematical theory somewhat complicated, but other considerations have been made to give way to the necessity of obtaining films which readily yield the black.

Preliminary experiments were instituted to test the observations of Lüdtge and van der Mensbrugghe as to difference of surface-tension between two films, one of which had been formed more recently than the other. These experiments showed that when one of the films was kept thick by supplying liquid to its upper support (flooding), while the other was allowed to thin, a considerable apparent difference of surface-tension was obtained. Before, however, this could be accepted as a trustworthy determination of an actual difference of surface-tension, several possible sources of error had to be considered. Thus, experiment shows (1) that the fact that the thicker film displays the greater surface-tension cannot be attributed to any peculiarity of the apparatus or mode of thickening adopted; (2) that it is not due to the weight of the thicker film; and (3) that only a small part of the observed difference can be ascribed to any slipping of the film over the liquid attachments to the solid supports.

The cause of the phenomenon cannot at present be assigned with certainty. Perhaps many causes are at work. Reasons are given for the conclusion that it is merely an instance of the difficulty which many observers have found in preserving a liquid surface pure.

On the assumption that the rapid change in the surface-tension of a newly-formed film is not due to its thinning, but to a disturbing cause, attempts were then made to eliminate this cause, or reduce it so as to compare films of very different thicknesses.

Two methods of attacking the problem were carried out. In the first the procedure was as follows:—The diameters of two cylindrical films were measured when they were in the same state; an electric current was passed up one of them in order to thicken it; and then, after a sufficient length of time had elapsed for the direct effect due to the disturbance produced by the current to pass off, the diameters were again measured. By this means it was possible to compare two films, one of which was nearly all black, while the other displayed a little black and the colours of the first and second orders. Both films were then allowed to thin, and assuming (in accordance with previous observations of the authors) that that which was already black remained in a constant state, any change of diameter which took place, as the coloured film became black, could be observed.

In a second group of experiments a cylinder was balanced against a sphere. As a spherical film thins more slowly than a cylinder, a comparison between a thick film (sphere) and a black or partially black film (cylinder) could be made without having recourse to an electric current, and greater differences of thickness were obtained than in the earlier observations.

The differences of surface-tension measured in these observations were very small. They never exceeded 1·5 per cent., and the black films were sometimes more and sometimes less curved than the thicker films with which they were compared. There was no evidence of any regular change in the surface-tension as the thickness diminished, and the average difference between the tension of the black and coloured films as deduced from fifteen experiments was only 0·13 per cent.

The general result of the inquiry, therefore, appears to be that *when the black part of a soap-film forms in the normal way, spreading slowly over the surface, no evidence of any change in surface-tension dependent on the thickness of the film is furnished by a direct comparison of the tensions of thin and thick films over a range of thickness extending from* 1350 *to* 12 *millionths of a millimetre.*

This conclusion is based upon a method of experiment by which a change of ½ per cent. in the value of the tension must have been detected, had it existed, and upon fifteen independent comparisons of the tensions of black and coloured films.

The authors next discuss the bearing of their observations upon the question of the magnitude of the so-called "radius of molecular attraction." They point out that if the mere equality in the surface-tensions of thick and thin films is to be considered conclusive, they have accumulated much stronger evidence for the statement that the radius of molecular attraction is less than half the thickness of a black film, *i.e.* $< 6 \times 10^{-6}$ mm. than Plateau produced for the assertion that 59×10^{-6} mm. is a superior limit to its magnitude. They are, however, unwilling to draw this conclusion from their experiments until an explanation is forthcoming in harmony with it, of the apparent discontinuity in the thickness of the film which always (except under very special circumstances) occurs at the edge of the black.

They are themselves inclined to look upon the sharp edge of the black as evidence of a change in surface-tension due to the tenuity of the film, and to regard the result of their experiments as fixing a superior limit (0·5 per cent.) to the difference of the tension of the black and coloured parts.

As no explanation of the discontinuity at the edge of the black has (as far as the authors are aware) ever been put forward, they conclude by a suggestion which, though no doubt of a speculative character, may serve to draw attention to a subject which is they believe of considerable interest.

They show that the main facts to be accounted for, viz. the discontinuity, the uniform thickness of the black, the wide variations in the thickness of the part of the coloured film which is in contact with the black, and the equality in the surface-tensions of the black and coloured films, could be explained if it were supposed that the surface-tension has a critical value when the thickness is somewhat greater than 12×10^{-6} mm.

The possibility of the existence of such a critical value has been pointed out by Maxwell (*Encycl. Brit.*, art. "Capillarity"). It would be explained by the assumption frequently made in discussions on the nature of molecular forces, that as the distance between two molecules diminishes, the mutual force between them is alternatively attractive and repulsive.

June 10.—"On some New Elements in Gadolinite and Samarskite, Detected Spectroscopically." By William Crookes, F.R.S., V.P.C.S.

The recent discovery by my distinguished friend M. de Boisbaudran (*Comptes rendus*, cii., p. 1003, May 3, 1886) of the existence of a new element which he calls Dysprosium, makes it unadvisable on my part, as a fellow investigator in spectroscopic research, to delay any longer the announcement of some of the results I have obtained during the fractionations of the samarskite and gadolinite earths.

I will first take the earths which give absorption-spectra when their solutions are examined by transmitted light. These occur chiefly at the higher end, beginning with didymium and proceeding, through samarium, holmium, &c., to erbium, which is one of the least basic. The earths which give phosphorescent spectra chiefly occur at the lower end, but each group overlaps the other; for instance, yttria occurs above erbia.

One of the highest of the absorption-spectrum earths is didymia. The spectrum of didymium, as generally met with, is well known, and is given in my paper on "Radiant Matter Spectroscopy: Part 2, Samarium" (par. 135).

It has long been suspected that didymium is not a simple body, and in June 1885 Dr. C. Auer announced that by a series of many hundred fractional crystallisations he had succeeded in splitting up didymium into two new elements, one giving leek-green salts and the other rose-red salts. The green body he called Praseodymium and the rose-red Neodymium. I have not found that my method of fractionation gives a decomposition similar to this; probably didymium will be found to split up in more than one direction, according to the method adopted; but by pushing the fractionations at the didymium end of the series to a considerable extent, a change gradually comes over the spectrum. At the lower end the earth gives an absorption-spectrum such as is usually attributed to didymium, but with no trace of some of the bands in the blue end, the one at λ 443 being especially noticeable by its absence. The intermediate earths give the old didymium spectrum, the relative intensities of some of the bands varying according to the position of the earth in the series, the band 443 becoming visible as the higher end is approached. The highest fractions of all give the band 443 one of the most prominent in the spectrum, being accompanied by other fainter bands which are absent in the lowest didymium spectrum.

I now come to a branch of the subject which promises to yield results even more fruitful than those given by the examination of absorption-spectra: I refer to the spectra yielded by some of the earths when phosphoresced *in vacuo*. This method has been so fully explained before the Royal Society, in my papers on "Radiant Matter Spectroscopy," that I need not repeat it.

In my Bakerian Lecture on Yttrium (*Phil. Trans.*, Part 3, 1885) I described the phosphorescent spectrum of this earth, and gave a drawing of it. In the Samarium paper I gave a similar description and drawing of the samarium spectrum, and also described and illustrated some anomalous results obtained when yttria and samaria were mixed together. Under the conditions described in the paper a sharp and brilliant orange line made its appearance, which at that time seemed as if it belonged to the samarium spectrum, and was only developed in greater intensity by the presence of yttria. This explanation, however, did not satisfy me, and I called the line $\left(\lambda\ 609 = \frac{1}{\lambda_2}\ 2693\right)$ "the anomalous line," intending to return to it at the first opportunity. I have since further investigated the occurrence of this line, with more than usual good fortune in the extent and importance of the new facts thereby disclosed.

Systematic fractionation was carried on with the portions of the general series giving the strongest appearance of line 609, and it soon became apparent that the line closely followed samarium. The presence of yttria was not necessary to bring it out, although by deadening the brightness of the other bands it was useful, not seeming to affect the line 609. Several circumstances, however, tended to show that although line 609 accompanied samarium with the utmost pertinacity, it was not so integral a part of its spectrum as the other red, green, and orange lines. For instance, the chemical as well as physical behaviour of these line-forming bodies was different. On closely comparing the spectra of specimens of samaria from different sources, line 609 varied much in intensity, in some cases being strong and in others almost absent. The addition of yttria was found to greatly deaden the red, orange, and green lines of samarium, while yttria had little or no effect on the line 609; again, a little lime entirely suppressed line 609, while it brought out the samarium lines with increased vigour. Finally attempts to separate line 609 from samarium, and those portions of the samarskite earths in which it chiefly concentrated, resulted in sufficient success to show me that, given time enough and an almost inexhaustible supply of material, a separation would not be difficult.

But what was then practically impossible to me, restricted with limited time and means, Nature has succeeded in effecting in the most perfect manner. I had been working on samarskite, and many observations had led me to think that the proportion of band-forming constituents varied slightly in the same earth from different minerals. Amongst others, gadolinite showed indications of such a differentiation, and therefore I continued the work on this mineral. Very few fractionations were necessary to show that the body giving line 609 was not present in the gadolinite earths, no admixtures of yttria and samaria from this source giving a trace of it. It follows, therefore, that the body whose phosphorescent spectrum gives line 609 occurs in samarskite, but not in gadolinite; thus it cannot be due to samarium, yttrium, or a mixture of these two elements; the only other probable alternative is that the source of this line is a new element.

Chemical fractionation is very similar to the formation of a spectrum with a very wide slit and a succession of shallow prisms. The centre portion remains unchanged for a long time, and the only approach to purity at first will be at the two ends, while a considerable series of operations is needed to produce an appreciable change in the centre.

During the later fractionations of the gadolinite earths another set of facts, formerly only suspected, have assumed consistent form. The spectrum bands which hitherto I had thought belonged to yttria soon began to vary in intensity among themselves, and continued fractionating increased the differences first observed. It would exceed the limits of a preliminary note were I to enter into details respecting the chemical and physical reasons which lead me to the definite conclusions I now bring before this Society. More than 2000 fractionations have been performed to settle this single point. I will content myself with stating the results. The earth hitherto called yttria appears to be a highly complex body, capable of being dissociated into several simpler substances, each of which gives a phosphorescent spectrum of great simplicity, consisting for the most part of only one line.

Taking the constituents in order of approximate basicity (the chemical analogue of refrangibility) the lowest earthy constituent gives a violet band (λ 456), which I have reason to believe belongs to ytterbia. Next comes a deep blue band (λ 482); then the strong citron band (λ 574), which has increased in sharpness till it deserves to be called a line; then come a close pair of greenish-blue lines (λ 549 and λ 541, mean 545); then a red band (λ 619), then a deep red band (λ 647), next a yellow band (λ 597), then another green line (λ 564); this (in samarskite yttria) is followed by the orange line (λ 609) of which I have already spoken; and finally, the three samarium bands remain at the highest part of the series. These for the present I do not touch, having my hands fully occupied with the more easily resolvable earths.

In the *Comptes rendus* for April 19, 1886, M. de Boisbaudran announced to the Academy that M. de Marignac, the discoverer of Yα, had selected for it the name Gadolinium. In February last I gave a short note on the earth Yα (*Proc.* Roy. Soc., No. 243, February 1886, and NATURE, vol. xxxiii., p. 525) in which I described its phosphorescent spectrum (agreeing exactly with that given by Yα of M. de Marignac's preparation). Referring to my paper it will be seen that Yα is composed of the following band-forming bodies:—(451), (549), (564), (597), (609), (619), together with a little samarium. Calling the samarium an impurity, it is thus seen that gadolinium is composed of at least four simpler bodies. The pair of green lines (λ 541 and λ 549, mean 545), being the strongest feature in its spectrum, may be taken as characteristic of gadolinium: the other lines are due to other bodies.

A hitherto unrecognised band in the spectrum by absorption or phosphorescence is not of itself definite proof of a new element, but if it is supported by chemical facts such as I have brought forward there is sufficient *primâ facie* evidence that a new element is present. Until, however, the new earths are separated in sufficient purity to enable their atomic weights to be approximately determined, and their chemical and physical properties observed, I think it is more prudent to regard them as elements on probation. I should therefore prefer to designate them provisionally by the mean wave-length of the dominant band. In this I am following the plan adopted by astronomers in naming the minor planets, which are known by a number encircled by a line. If, however, for the sake of easier discussion among chemists a definite name is thought more convenient, I will follow the plan frequently adopted in such cases, and provisionally name these bodies as shown in the following table:—

Position of lines in the spectrum	Mean wave-length of band or line	Provisional name	Probability
Absorption-bands in violet and blue	443	Dα	New.
	451·5	Sα	Dysprosium.
	475	Sβ	New.
Bright lines in—			
Violet	456	Sγ	Ytterbium.
Deep blue . .	482	Gα	New.
Greenish - blue (mean of a close pair .	545	Gβ	Gadolinium.
Green	564	Gγ	New.
Citron . . .	574	Gδ	New.
Yellow . . .	597	Gε	New.
Orange . . .	609	Sδ	New.
Red	619	Gζ	New.
Deep red . .	647	Gη	New.

The initial letters D, S, and G recall the origin of the earths respectively from Didymium, Samarskite, and Gadolinite.

Geological Society, May 26.—Prof. J. W. Judd, F.R.S., President, in the chair.—John Allen Brown was elected a Fellow of the Society.—The following communications were read:—Further proofs of the pre-Cambrian age of certain granitoid, felsitic, and other rocks in North-Western Pembrokeshire, by Henry Hicks, M.D., F.R.S., F.G.S. In this paper the author gave the results obtained by him during a recent visit to North-West Pembrokeshire. He stated that he had further examined some of the sections referred to in his previous papers, as well as others not therein mentioned, and that he had obtained many additional facts confirmatory of the views expressed by him in those papers. The Lower Cambrian conglomerates and grits, he said, contained pebbles of nearly all the rocks in that area which he had claimed as of pre-Cambrian age; and the fragments of the granitoid rocks, the felsitic rocks, the halleflintas, and of the various rocks of the Pebidian series which he had found, showed unmistakably that those rocks had assumed, in all important particulars, their peculiar conditions before the fragments were broken off. Moreover, he stated that there was abundant evidence to show that the very newest of the pre-Cambrian rocks of the area had been greatly crushed, cleaved, and porcellanised before any of the Cambrian sediments were deposited; hence he maintained that there was in the area a most marked unconformity at the base of the Cambrian. At Chanter's Seat, near St. David's, he found that the Lower Cambrian grits and conglomerates were, in parts, almost wholly made up of fragments of characteristic varieties of the granitoid rocks which form the Dimetian ridge near by. The so-called granite of Brawdy, Hayscastle, and Brimaston, he said, there was good evidence to show, was probably of the age of the granitoid rocks of St. David's. The mass of so-called granite near Newgale, he stated, was composed of rhyolities and breccias, undoubtedly of pre-Cambrian age. The Roch Castle and Trefgarn rocks, he stated, could not possibly be intrusive in Cambrian and Silurian strata, but belonged to a series of pre-Cambrian rocks. He referred to the important evidence bearing on the age of these rocks given in a paper communicated to the Society, since his last paper was read, by Messrs. Marr and Roberts. These authors showed that in a quarry near Trefgarn Bridge a Cambrian conglomerate, overlain by Olenus-shales, is to be seen resting on the eroded edges of the Trefgarn series. The author examined this section lately, and obtained from the conglomerate some very large pebbles of the characteristic rocks called hälleflintas, and of the ash-bands, both of which are found *in situ* in the quarry. He therefore maintained that there was the most ample evidence to show that there was a great group of pre-Cambrian rocks exposed in North-West Pembrokeshire, and hence that he had proved conclusively that Dr. Geikie's views in regard to these rocks, as given in his paper and more recently in his text-book, are entirely erroneous.—On some rock-specimens collected by Dr. Hicks in North-Western Pembrokeshire, by Prof. T. G. Bonney, D.Sc., LL.D., F.R.S., F.G.S. The author stated that he had examined microscopically a series of specimens collected by Dr. Hicks, and compared them with those described by Mr. T. Davies, in vol. xl. of the *Quarterly Journal*, and with some in his own collection. He agreed with Mr. Davies's conclusions in all important matters. The Chanter's Seat conglomerate contained many grains of quartz and felspar, curiously like those minerals in the so-called Dimetian, together with numerous small rolled fragments, about a quarter of an inch in diameter, exactly resembling the finer-grained varieties of that rock, besides bits of felsite, similar to some which occur in the St. David's district, quartzite, a quartz-schist, and an argillite. The rocks *in situ* in the Trefgarn quarry were indurated trachytic ashes, together with the curious flinty rock which was the most typical of the so-called hälleflintas. One of the pebbles from the overlying conglomerate perfectly corresponded with the last-named rock; others appeared to be most probably from an altered trachytic ash, differing only varietally from those *in situ*. After prolonged examination of this "hälleflinta" of Trefgarn and the similar rocks from Roch, he was of opinion that while it was possible that some specimens might be altered ashes, most of them were originally rhyolites or obsidians, devitrified, and then silicified by the passage of water which had contained silica in solution. The Trefgarn group obviously could not be intrusive in the Lower Cambrian, and it was extremely improbable that the Roch Castle series was newer than the basement conglomerate of that district. The Brawdy granitoid rock might be a granite, but at any rate it presented considerable resemblance to the "Dimetian." It was therefore evident that the Cambrian conglomerate of St. David's was formed from a very varied series of rocks, some of them much older than it, and that the Dimetian could not be intrusive in it. Moreover, even if the Dimetian should be proved ultimately to be a granite, and the core of a volcano which had emitted the rhyolites, sufficient time must have elapsed after its consolidation and prior to the making of the conglomerate to remove, by denudation, a great mass of overlying rock. Hence, whatever its nature, it was pre-Cambrian.—On the glaciation of South Lancashire, Cheshire, and the Welsh border, by Aubrey Strahan, F.G.S., H.M. Geological Survey. By permission of the Director-General. The author stated that it may be concluded that (1) the striæ on the English and Welsh sides respectively, while showing variations among themselves, by a marked preponderance in one quarter of the compass, indicate a direction of principal glaciation, this direction being on the English side from about N.N.W., and on the Welsh from about E.S.E. (2) The direction of glaciation in both districts agrees very closely with that of the transportation of the drift, but is only locally influenced by the form of the ground. (3) The striæ are by no means universal, but are found almost exclusively in connection with those beds in the drift which contain evidence of the actual presence of ice. The striæ are not such as can have been produced by valley-glaciers; they go across and not down the valleys, nor are there any moraines. The marine origin of the drifts is indicated by their well-marked stratification as a whole, by the alternations of well-washed sands and gravels with the Boulder-clays, and by the occurrence through all the beds of marine shells.

Royal Microscopical Society, May 12.—The Rev. Dr. Dallinger, F.R.S., President, in the chair.—The President referred to the death of Dr. J. Matthews, a member of Council, and a resolution of sympathy and condolence with the family was adopted.—Mr. J. Mayall, jun., exhibited and described a new pattern of the radial microscope by Mr. Swift, in which a rack was added to the arc, and a removable mechanical stage provided by which the object was clipped without any intermediate plate.—Mr. J. D. Hirst's communication was read referring to the report in the *Journal* of the Royal Society of N.S. Wales, attributing to him the view that a highly refractive mounting medium enabled objectives of small aperture to compete in resolution with wide-angled oil-immersion objectives. Mr. Hirst explained that the report was so worded as to convey a totally erroneous impression of what he claimed, which was only that the highly refractive medium would render difficult test diatoms so easy to a good high angled water lens that the superiority of the oil-immersion objective will not be apparent, except under the very deepest eye-pieces.—Mr. C. D. Ahrens's paper, on a new polarising prism, was read; also Prof. Thompson's letter in commendation of it as unrivalled for use as a polariser, having flat ends, wide angle, and absence of distortion or coloured fringes.—Dr Sternberg's paper on *Micrococcus pasteuri* was read, in which he called attention to the characters which distinguish it in a very definite manner from the microbe of fowl-cholera, it differing from the latter, not only in its morphology, but in the fact that it is not fatal to fowls.—Mr. F. H. Evans exhibited some photomicrographs produced by the Woodburytype process from negatives by himself, and transferred

to glass for lantern illustration. They were shown upon a portable screen by Mr. G. Smith of the Sciopticon Co. Mr. Evans claimed that he had been more than ordinarily successful in overcoming the chief difficulty in the matter, that of obtaining such a focus as would properly represent the various planes of even deep objects, and this without loss of natural effect. The objects illustrated comprised Diatoms and Desmids, Foraminifera, Polycystina, star-fishes, sections of Echinus spines, insect preparations, animal parasites, and anatomical and vegetable sections, the remarkable clearness of most of the photographs calling forth frequent favourable comments from the Fellows present.

Entomological Society, June 2.—Mr. R. McLachlan, F.R.S., President, in the chair.—The following gentlemen were elected Fellows, viz. Mr. C. Baron-Clarke, M.A., F.R.S., Mr. Dannatt, Mr. H. Wallis-Kew, Mr. J. P. Mutch, Mr. B. W. Neave, Mr. A. C. F. Morgan, and Mr. W. Warren, M.A.—Mr. Stevens exhibited an example of *Heydenia auromaculata*, from the Shetlands, a species new to Britain.—Dr. Sharp exhibited certain specimens of *Staphylinidæ*, specially prepared and placed in cells of cardboard, sealed up with layers of bleached shellac.—Mr. Billups exhibited *Meteorus luridus*, Ruthe, a species of *Ichneumonidæ* new to Britain.—Mr. W. White exhibited cocoons of *Cerura vinula*, and made some observations as to the mode by which the perfect insect escapes from these solid structures. He thought that formic acid secreted by the insect was a probable factor in the operation. The question of how the parasitic *Ichneumonidæ* and *Diptera* escaped from these cocoons was also raised, and the President, Baron Osten-Sacken, Mr. Waterhouse, and Prof. Meldola, made remarks on the subject.—Mr. Elisha exhibited living larvæ of *Geometra smaragdaria*, from the Essex marshes. He also exhibited the singular pupæ of *A. bennettii*.—Mr. Howard Vaughan exhibited a long series of *Peronea hastiana*, showing the innumerable varieties of the species. He also exhibited, on behalf of Mr. Sidney Webb, of Dover, an interesting series of *Cidaria suffumata*, and read notes on the varieties of this species, communicated by Mr. Webb. Mr. Jenner-Weir, Mr. Waterhouse, Dr. Sharp, Mr. Distant, and Mr. Stainton took part in the discussion which ensued.—Mr. A. G. Butler communicated a paper on new genera and species of *Lepidoptera-Heterocera* from the Australian region, in which 21 new genera, and 103 new species were described.—Dr. Baly communicated a paper on uncharacterised species of *Diabrotica*.

EDINBURGH

Mathematical Society, June 11.—Dr. R. M. Ferguson, President, in the chair.—Mr. Alexander Robertson discussed a problem in combinations.—Mr. John Alison gave a mnemonic for a group of trigonometrical formulæ.—Mr. A. Y. Fraser read a communication from Mr. George A. Gibson on integration by parts and successive reduction.

PARIS

Academy of Sciences, June 7.—M. Jurien de la Gravière, President, in the chair.—Remarks on the works of M. Jean Claude Bouquet, by M. Halphen. To this notice is appended a list of the scientific writings of the illustrious mathematician, who was born at Morteau, Franche-Comté, on September 7, 1819, and died on September 9, 1885.—A new method of determining the refractions of light at all altitudes by means of the known value of one alone (continued), by M. Lœwy. The formulas are here given by which various refractions may be found after one has been determined by the method already explained.—On the part played by Lavoisier in determining the unit of weight in the metrical system, by M. C. Wolf. The imperfect data contained in Delambre's "Base du Système Métrique" are here supplemented from fresh documents tracing the action of Lavoisier in determining the various standards of weight in the metrical system adopted by the French Government at the close of the last century.—Heat of combustion and formation of the sugars, hydrates of carbon, and allied polyatomic atoms, by MM. Berthelot and Vieille. By their new method the authors have at last succeeded in effecting complete combustion of the sugars by free oxygen, thereby correcting the determinations already obtained by Rechenberg with the chlorate of potash for mannite, dulcite, lactose, saccharose, cellulose, and some other substances.—Fresh observations on the ammonia present in the ground, by MM. Berthelot and André. In reply to M. Schlœsing's last note the authors deal with the interesting problems suggested by that chemist's remarks on the laws regulating the interchange of ammonia between the atmosphere and the earth.—On the atomic weight and the spectrum of germanium, by M. Lecocq de Boisbaudran. Under the induction-spark a fine specimen of this element received from M. Winkler yields a beautiful spectrum with remarkably bright blue and violet rays, with atomic weight 72·27. Germanium would therefore appear to lie, not between bismuth and antimony, as at first supposed, but between silicium and tin, like the ekasilicium of Mendelejeff's classification. Winkler had fixed its atomic weight provisionally at 72·75.—Note on the age of the Pikermi, Mount Leberon, and Maragha fauna, by M. Albert Gaudry. The author's observations induce him to refer this geological epoch rather to the Middle than to the Upper Tertiary.—Researches on gelatine, by M. P. Schutzenberger.—Influence of the anæsthetic vapours on the living tissues, by M. R. Dubois. The paper gives a description of the action exercised by the vapours of chloroform, ether, sulphuret of carbon, and alcohol on the protoplasm of the animal and vegetable tissues. The action is regarded not so much as one of coagulation, as of substitution analogous to that obtained by Graham when studying the effects of ether, alcohol, &c., on the mineral colloidal hydrates.—Observations of the comet *c* (1886) made at the Observatory of Lyons with the Brunner six-inch equatorial, by M. Gonnessiat.—Note on the herpolhodie, by M. Hess.—Extension of the general law of solidification to thymol and napthaline, by M. F. M. Raoult. The figures 0·61 and 0·64, here determined for these two substances, approach as nearly as possible to 0·62 given by the author's general law of solidification announced some years ago.—On a visual illusion and the apparent oscillation of the stars, by M. H. de Parville. The phenomenon of the apparent motion of slightly illumined bodies in the midst of darkness is here associated with that of the apparent motion of the stars known to the Germans by the name of *Sternschwanken*.—Action of the hydrogenated acids on vanadic acid, by M. A. Ditte.—Action of the oxide of lead on the hydrochlorate of ammonia, by M. F. Isambert. This reaction, which absorbs heat, is shown to be entirely analogous to a phenomenon of dissociation, and controlled by the ordinary laws of dissociation.—Note on the molybdate of cerium, by M. Alph. Cossa. The form of this substance prepared by different processes by the author and M. Didier, confirms the strict analogy of molecular structure between certain combinations of the metals of cerite and the corresponding combinations of calcium and lead.—Note on a new alloy of aluminium, by M. Bourbouze. This useful alloy, consisting of 10 parts tin and 100 aluminium, is white, and has rather a higher density (2·85) than the pure metal.—On the presence of cholesterine in some new fatty substances of vegetable origin, by MM. Ed. Heckel and Fr. Schlagdenhauffen.—On the presence of cholesterine in the carrot; researches on this direct principle, by M. A. Arnaud. The cholesterine yielded by the carrot contains: carbon, 83·90; hydrogen, 12·20; oxygen, 3·90. It is insoluble in water, but very soluble in boiling alcohol, in the sulphuret of carbon, chloroform, and oils. It thus differs little from animal cholesterine, and is absolutely identical with the substance derived by Hesse from the Calabar bean.—Note on piliganine, the alkaloid of Lycopodiacea from Brazil, by M. Adriau. The piligan plant, which yields this principle, is a lycopod closely allied to the European *L. Selago*, and probably the variety known in Brazil as *L. Saussurus*. The extract is a strong poison, soluble in water, in alcohol, and chloroform.—Researches on the vegetable development of the sugar beetroot, by M. Aimé Girard.—On the crystalline form of the pyrophosphates and hypophosphates of soda, by M. H. Dufet.—On anthophyllite, an orthorhombic amphibole with two prismatic cleavages, *m* (110) ($mm = 125°$ about), and a third, *h'* (010), by M. A. Lacroix.—On the development of the elements of the gray cortical substance of the cerebral circumvolutions, by M. W. Vignal.—On a chronometer with magnetic coupling, by M. A. d'Arsonval. This is an apparatus constructed at the suggestion of M. Brown-Séquard for the purpose of determining the velocity of sensitive impressions transmitted through the spinal marrow in a normal or pathologic state.—Note on sacculine, by M. Y. Delage. The author replies to the objections recently urged by M. Giard against some of the results announced by him on the evolution of sacculine.—On the internal air of insects compared with that of plants, by M. J. Peyrou.—On the stratigraphic structure of the Sierra Nevada and Sierra de Ronda, South Spain, by MM. Ch. Barrois and Alb. Offret.—On the geology of the Central Tunisian region between Kef and Kairwan, by M. G. Rolland.—On the genus *Bornia*, F. Rœmer, one of the most charac-

teristic fossil plants of the Kulm and Upper Devonian formations, by M. B. Renault.

BERLIN

Physiological Society, May 14.—Dr. Kossel reported on experiments instituted by Dr. Kaske in the chemical division of the Physiological Institute, under his superintendence, on the chemical composition of the brain of the embryos of horned cattle. The occurrence of definite chemical substances, for example, elastine, keratine, cerebrine, in altogether special tissues, made it appear desirable to establish whether, during the process of development, the chemical composition or the morphological structure was the primary. Seeing that the brain of the embryo was very lymphatic, the composition and quantity of the lymph, which saturated all tissues of the embryo, were first ascertained and subtracted from the collective mass. The values found in two brains were compared with the results of the chemical investigation of brains carried out a considerable time ago in the laboratory of Prof. Hoppe-Seyler. The investigation referred to had shown that the gray substance of the brain of full-grown cattle differed essentially from the white substance. The gray substance, in the first place, contained but very little cerebrine, probably none at all; the white substance, on the other hand, contained more than 9 per cent. of the dry material. The gray substance was further distinguished from the white by its less amount of cholesterine and its greater quantity of albumen and extractives. In the defect in cerebrine, in the small amount of cholesterine, and in the copious supply of albumen and extractives, the brains of the embryos of horned cattle held exactly the same position as did the gray substance of grown-up brains. It was only in the quantity of lecithine and of salts that the embryonal brains demonstrated any difference from the gray substance. The embryonal brain was, therefore, very essentially distinguished from the white substance—a phenomenon in harmony with the fact that in the embryonal brain medullated nerve-fibres were not met with.—Prof. Christiani handed in his book published last year, "Zur Physiologie des Gehirns," and added some statements in corroboration of the view there set forth regarding the power of seeing on the part of rabbits after complete extirpation of Munck's sphere of vision. Prof. Gudden and Prof. Luciani had also, he said, found animals which after such operations had yet the power of sight. He sharply defined the difference between Prof. Munk and himself by saying that the former maintained an animal *must* be totally blind after excision of the sphere of vision on both sides, whereas his own observations allowed him to take up the position only that an animal after such an operation *might* get totally blind.—Dr. Virchow communicated the results of the investigations carried out by Herr Canfield, in the Anatomical Museum, into the accommodation apparatus of a bird's eye. In order to get at a knowledge of the physiological process of accommodation in the highly developed bird's eye, the anatomical substratum required to be gained. The investigation brought to light, in point of fact, a very long series of differences in the arrangement and development of the different formations of the apparatus situate between cornea, sclera, lens, and iris, among the different species of birds, great horned owl, owl, starling, dove, goose, and others. These differences the speaker illustrated by drawings, but no physiological explanation of them had yet been arrived at.—Dr. Gossels had made experiments regarding the secretion of nitrates through the urine in men and birds (duck and fowl), the nutriment administered having been in every case the same, nitrates being in some instances given, and also in some instances not given. By these experiments it was demonstrated that, in the case of animals secreting uric acid, a large part of the nitrates that had been partaken was again excreted, but that a still larger part disappeared in the body. As to what became of these latter nitrates, the speaker was not disposed to set up any hypothesis.—Prof. Zuntz, referring to the latter point, observed that several years ago it had been noticed in his laboratory that, after partaking of nitrate of ammonia, animals exhaled free nitrogen. A part at least of the nitrates, therefore, in accordance with this observation, was decomposed in the body and reduced to free nitrogen.

STOCKHOLM

Geological Society, March 4.—Hr. C. W. Crongvirt gave an account of the formation of iron ochre in some little lakes in the province of Helsingland. The lakes drew their water from the surrounding iron-containing streams. The yellow ochre seemed to collect on the clay, and the brown on the sand-bottom of the lakes. A factory has been started for its utilisation.—Prof. W. C. Brögger gave an account of the Olenell zone of North America, maintaining that this zone, with its peculiar fossils, which in several instances seemed to be the original types for varieties subsequently appearing, did in America—as well as had been long known to be the case in Scandinavia—occupy a very low place in the geological strata below the true Paradoxide slate.—Hr. F. Tegræus gave an account of his studies of the glacial formations on the Island of Gothland, in the Baltic. He stated that blocks and drifts proved that the glaciers had first moved in a south-westerly and afterward in an easterly direction. He had never found true ridges on the island, but certainly shore-terraces and terminal moraines.—Hr. E. Svedmark exhibited a specimen of argyrodite sent by Prof. Norkenskjöld, which contains the newly discovered element germanium.

THURSDAY, JUNE 24, 1886

MR. MINCHIN'S TREATISE ON STATICS

A Treatise on Statics, with Applications to Physics. By G. M. Minchin, M.A. Vol. II. 3rd ed. (pp. 512 + vi.). Clarendon Press Series. (Clarendon Press, Oxon, 1886.)

THIS new edition of this work has been separated into two volumes. The first volume (351 pp.), dealing with "Equilibrium of Coplanar Forces," aims at the standard of Undergraduate Honours; it is noticeable for the frequent use of graphic methods and for a long discussion on funicular polygons (now forming so important a help in graphic applications to engineering); this was published in 1884. The second and longer volume is a masterpiece of constructive skill in the adaptation of modern methods; it is particularly noticeable for the introduction of the theory of screws and of astatic equilibrium, also for an extensive selection of excellent examples, and for the free use of hyperbolic and elliptic functions in solutions: the reading required is thus considerable; it is, in fact, intended for those who seek Honours. The work is so much improved in this edition that it merits an extended notice. The second volume is divided into only seven chapters, each of which is an essay on its special subject. The numbering of chapters and articles is continuous with Vol. I., whilst the pagination is distinct.

Chapter XIII. (the leading chapter, 64 pp.) deals with Non-Coplanar Forces, and contains the usual propositions (16 pp.) about compounding and resolving forces and couples, about resultants, equilibrium, and central axis: then follow (48 pp.) the theory of screws, cylindroids, complexes, and degrees of freedom; the constructions given for the cylindroid are neat: in one the surface is traced by the blades of a pair of scissors, which open horizontally at a uniform rate, whilst the rivet falls vertically; this gives a vivid idea of the surface.

Chapter XIV. (34 pp.) treats of Astatic Equilibrium, which is defined to be a balance amongst forces of fixed magnitudes and directions at definite points of a body subject to displacement. This is treated by quaternions, the Cartesian method being found cumbrous. It is shown that a system of forces can always be astatically balanced by a set of *three* forces in any given directions (and even by three equal rectangular forces) applied at three points lying in a plane fixed in the body, and also by two forces if these points lie in a line, or by one force if they coincide (the general proof of all this is easy by elementary methods). This subject has some practical application in electrical measurements, for which an astatic magnet-pair is much used, and in seismometry, for which it has been sought to make pendulums astatic for small displacements (see Milne's new work on "Earthquakes," p. 26).

Chapter XV. (91 pp.) treats of Virtual Work. The term "work-coefficient" has here been with great advantage introduced to replace the lengthy and *incorrect* term "generalised component of force." Lagrange's method is treated of at length: its advantage is shown to consist in reducing all problems to the case wherein the displacements are independent, by introducing internal forces to represent the constraints. One disadvantage is its undue length, most marked in simple cases. Another is a decided risk of error in estimating the work of the internal forces; instances of error due to this in Lagrange's researches are shown, *e.g.* the cases (1) of an inextensible surface wherein Lagrange assumes (incorrectly) that $\delta dS = 0$ fully expresses the inextensibility; and (2) of an extensible surface wherein he assumes (incorrectly) the work of internal deformation to be simply proportional to dS; and (3) of an elastic wire wherein Lagrange overlooks the distortion. A brief summary of Jellett's researches on inextensible surfaces is given, and it is shown that such a surface is quite determinate (and therefore not deformable) if any bounding edge of it be fixed, except it be anticlastic or developable, which latter admit of deformation when certain edges only on them are fixed. The surface-tensions of liquid-films are investigated (12 pp.), and the experimental way of producing several such forms is given, and their stability discussed.

Chapter XVI. (45 pp.). On Strings and Springs.—The properties of strings in general, also on rough and smooth surfaces, are discussed, with some cases of the extensible string; next those of plane elastic rods and plane springs; lastly, those of a twisted wire (20 pp.): this last is important in electrometers. The interesting *kinetic* analogies are shown (1) of a plane elastic rod with the simple pendulum, and (2) of a bent and twisted uniform wire with a heavy mass moving about a fixed point, viz. that the differential equations in the analogous problems are similar.

Chapter XVII. (123 pp.), on Attraction, is divided into four sections.

Sec. I. (29 pp.). On Attraction in General.—It is explained that the law of gravitation implies that the attracting particles must be very small compared with their distance. Notice is most usefully drawn to this limitation several times in the sequel, *e.g.* it is shown that the Cartesian expressions *seem* to give indeterminate attraction for very close points; also that for attractions more rapid than $1/r^2$ the attraction on an internal point is really infinite.

Sec. II. (40 pp.). On Potential.—In the definition the usual idea of motion from infinite distance has been dropped, and the definition runs as the work done in bringing a tiny mass from a position of zero attraction, &c. (not from infinity): this is much better. The continuity of the gravity-potential and of its first derivatives, the discontinuity of its second derivatives, the absence of maxima or minima thereof in empty space, and the instability of equilibrium under gravitation to several masses are shown. The application of the method of inversion is given; and, amongst many examples, Thomson's solution of the attraction of a spherical shell whose density $\propto$ (distance)^3.

Sec. III. (13 pp.). On Ellipsoids. After the usual investigation of their attraction, it is shown that the surfaces of prolate and oblate spheroids are not equipotential: various problems interesting in the figure of the earth are given.

Sec. IV. (42 pp.). Spherical Harmonics.—Green's equa-

tion is deduced and its consequences investigated, especially in helping to find potential. Spherical Harmonics occupy the next thirty-two pages. The very convenient and appropriate name "Laplacian" is here assigned to the important "Laplace's coefficients": by analogy the name "Legendrian" might well be applied to Legendre's coefficients; short terms of this kind are useful, and commemorate the inventors. The usual developments are given; the applications to symmetric bodies are interesting, *e.g.* a potential function (*i.e.* one such that $\nabla^2 v = 0$), which is the potential of a symmetric body for all points on its axis, is *the* potential of the body.

Chapter XVIII. (103 pp.), on Small Strains and Stresses, is divided into three sections.

Sec. I. (32 pp.). Small Strains.—This treats of the *small* strains (changes of shape or size) of a body without reference to their causes. It is shown that straight lines, planes, and parallels remain such, whilst spheres become ellipsoids, &c., and there is always one line of no rotation at every point. It is also shown that every strain may be resolved into a pure strain and a rotation, and that the strain proper may be produced by three elongations, or by one elongation and a contraction all round an axis (this is called traction). Torsion is shown to be equivalent to shear, and shear to be equivalent to an extension and contraction, &c.

Sec. II. (22 pp.). Stress.—This treats of internal stress apart from concomitant strain The usual composition and resolution are investigated, the work of an actual strain and the virtual work of virtual strain are found, and the latter is shown to be an exact differential.

Sec. III. (49 pp.). Stress and Strain.—The relations between the moduli of compression (k) and distortion (μ), the contraction-coefficient (η), and Young's modulus (k) are first traced for isotropic bodies, and the strain- and stress-potentials found for the same, and it is shown that every force-system produces definite strain. The work in pure compression and pure twisting is investigated, and it is shown that twisting couples applied at ends of a cylinder produce pure torsion only in a circular cylinder, so that in other cases the plane sections are deformed. The theory of the slightly bent plane beam is investigated as far as the theorem of three moments. In heterotropic bodies it is shown the conservation of energy reduces the number of independent elasticity-coefficients from thirty-six to twenty-one. St.-Venant's reduction to fifteen for cases where the mutual action of two particles is independent of other particles is discussed, and is shown to lead to the value $\eta = \frac{1}{4}$ for the lateral contraction-coefficient of an isotropic body. Maxwell's researches on the propagation of gravitation are reproduced, and are described as showing that gravitation could be produced by a certain stress over a closed surface propagated through an all-pervading medium (ether) transferring strain like a solid, but further research shows that this ether is not quasi-solid.

Chapter XIX. (45 pp.). Electrostatics.—After the usual elementary propositions it is shown that a "line of force" meeting an electrified conductor obliquely is refracted, and that the charge-distribution over an isolated body is determinate: this leads to interesting problems in soap-bubbles. It is shown from Green's equation that a hollow conductor screens its contents from outer electric disturbance; this has a practical application in protection of delicate instruments inside a metallic cage. Lastly, the theory of electric images is discussed, and examples given.

From the full analysis given it will be seen that the work is a most important one: it is, in fact, one of the best treatises of the day.

ALLAN CUNNINGHAM, Major, R.E.

THE CRUISE OF THE "BACCHANTE"

The Cruise of Her Majesty's Ship "Bacchante," 1879-82. Compiled from the Private Journals, Letters, and Note-books of Prince Albert Victor and Prince George of Wales, with Additions by John N. Dalton. Two Vols. (London: Macmillan and Co., 1886.)

To us the chief interest of these two bulky volumes lies in the fact that they are the record of what we may call the technical education of our future King and his brother. It was a right and proper thing for the Prince of Wales to do to see that his sons should become personally acquainted with the leading sections of that great Empire with the conduct of which they will in the future have so much to do. Indeed, in these times, when our colonies are coming so conspicuously to the front, when their affairs are regarded as of Imperial importance, it might be a good thing to insist that our Colonial Secretaries should follow the princes' example, and that no one should be considered qualified for the post of Minister for the Colonies who had not studied their affairs on the spot. Technical education is considered essential nowadays to any one occupying a responsible position in even the humblest of callings; but we fear that statesmanship is still beyond the pale of science.

In the volumes before us Canon Dalton has the lion's share. The princes' contributions have been edited by him from their diaries, note-books, and letters; while he himself contributes long sections in which he brings together much useful information, and discussions on the affairs of the various colonies visited. Of course the writings attributed to the princes are no doubt much indebted to the superintendence of their tutor; at the same time the boyish hands can be traced throughout. The whole work is creditable both to the princes and to Canon Dalton. They certainly worked hard both at their books and at their duties as middies; for in all respects when on board ship they were treated precisely as their mates. They evidently took a genuine interest in their duties on board; took a pride in mastering all the details of navigation and the working of a war-ship like the *Bacchante*: were as eager to pass their examinations as if their future careers depended on the result. Much of their share of the work consists of details as to the day's cruise, their own work as officers, the exercises proper to such a ship, and the incidents of the gun-room. Mixed up with this are the results of their own observations in the countries visited, information gathered during their visits or from books, their experiences when sojourning in the colonies, in Japan and other countries, with occasional reflections suggested by all this. Canon Dalton's contributions are more solid and serious. He enters into

long details on the history and present condition of the colonies, referring at length to the various questions that are uppermost in each, giving as a rule fairly the views of the various parties, though by no means abstaining from showing his own leanings. Certainly the work contains a vast amount of useful statistical, historical, industrial, and commercial information on our colonies, and will be found of service to any one desirous of getting up the subject. Of course it is not to be expected that a work like this will contain much that is novel or of scientific value. In Japan the princes indeed saw a great deal which is not likely to come in the way of the ordinary visitor; while a large portion of the second volume is devoted to Egypt and the Holy Land, which they explored under the guidance of such specialists as Capt. Conder and Sir Charles Wilson, and therefore are able to record much of real and almost unique importance in the geography and antiquities of those interesting countries.

What can Canon Dalton mean by permitting the insertion of the following entry, without note or comment? The apparition is stated to have been seen on the passage from Melbourne to Sydney:—

"July 11.—At 4 a.m. the *Flying Dutchman* crossed our bows. A strange red light as of a phantom ship all aglow, in the midst of which light the masts, spars, and sails of a brig 200 yards distant stood out in strong relief as she came up on the port bow. The look-out man on the forecastle reported her close on the port bow, where also the officer of the watch from the bridge clearly saw her, as did also the quarterdeck midshipman, who was sent forward at once to the forecastle; but on arriving there no vestige nor any sign whatever of any material ship was to be seen either near or right away to the horizon, the night being clear and the sea calm. Thirteen persons altogether saw her, but whether it was *Van Diemen* or the *Flying Dutchman* or who else must remain unknown. [Here are a few German verses on the phantom ship.] The *Tourmaline* and *Cleopatra*, who were sailing on our starboard bow, flashed to ask whether we had seen the strange red light. At 10.44 a.m. the ordinary seaman who had this morning reported the *Flying Dutchman* fell from the foretopmast crosstrees on to the topgallant forecastle and was smashed to atoms. At 4.15 p.m. after quarters we hove to with the headyards aback, and he was buried in the sea. He was a smart royal yardman, and one of the most promising young hands in the ship, and every one feels quite sad at his loss."

Then follows a statement about the admiral having been "struck down," as if it had some connection with the apparition.

The cruise of the princes, which lasted from September 1879 to August 1882, was divided into two well-marked sections. The first, extending to May 1880, included visits to Gibraltar and the Mediterranean, Madeira, the Canaries, West Indies, and Bermudas. After a long visit to Vigo, the second part of the cruise was begun in August 1880. By Ferrol, Madeira, and the Cape Verde Islands the River Plate was made, where some time was spent ashore. After touching at the Falkland Islands, a run was made to the Cape, where several weeks were spent, during which the princes visited several parts of Cape Colony, and showed special interest in the Observatory under Dr. Gill. In the spring of 1881 a long, stormy, and dangerous run was made across the southern Indian Ocean to Cape Leeuwin in West Australia, where the *Bacchante* was compelled to remain some time on account of damage to her rudder. This gave the princes an opportunity of becoming familiar with the peculiar geographical conditions of West Australia, and seeing the actual conditions of colonial life. Then followed long visits to South Australia, Victoria, New South Wales, and Queensland. Some time was spent in the Fiji Islands, of which the princes saw a good deal. Thence a straight run was made for Japan, where the princes had a very busy time indeed in visiting the many sights of that interesting country. Touching at Shanghai, Canton, and the Straits Settlements, the *Bacchante* reached Ceylon, where the princes met Prof. Haeckel, and showed a good deal of interest in him and his work. Then up the Red Sea to Egypt, where and in Palestine three months were spent, months of pretty hard work for the princes. Touching at Greece, Crete, Ceylon, Sicily, and Gibraltar, the *Bacchante* passed out of the Mediterranean and reached home on August 5, 1882, after a cruise during its whole commission of 54,679 miles. There are numerous attractive illustrations in the book, one small map of the world, showing the route, and numerous sectional charts drawn by the princes themselves.

OUR BOOK SHELF

Dogs in Health and Disease, as Typified by the Greyhound. By J. S. Hurndall. Pp. vii. + 81. (London: E. Gould and Son, 1886.)

Dogs: their Management and Treatment in Disease. By G. Ashmont. Pp. v. + 212. (London: Sampson Low, 1885.)

THE first of these two manuals is intended to assist owners of dogs in diagnosing the complaint from which the animal is suffering, and to suggest remedies which may be applied until professional advice can be secured. The book advocates the "homœopathic" system of treatment, and the first twenty-five pages are devoted to a general exposition of this system "in simple unconventional language."

The second book is much fuller in detail, and is evidently suitable as a hand-book for the veterinarian; the mode of treatment differs very considerably from that recommended in Mr. Hurndall's manual, but we must leave to those practically acquainted with the subject the decision as to the relative merits of the two systems. The section relating to hydrophobia is naturally of interest at present; this disease is more fully treated than any other, though the author points out its extreme rarity; nevertheless it is admitted that the danger to persons bitten by a really mad dog is considerable—one-third to four-fifths of the cases, according to whether the wound has or has not been cauterised, are said to be fatal. On the other hand, Mr. Hurndall (p. 52) quotes eighty cases of persons bitten by mad animals, of which not a single one terminated fatally.

The section relating to parasites is somewhat meagre, though the author may be right in saying that the study of these animals more nearly concerns the zoologist than the veterinarian. These principles are perhaps carried a little too far when *Ascaris marginata* is spoken of as a "lumbricoid" which "resembles the common earthworm." The book is carefully written, and free from obvious misprints, but the large amount of matter compressed into a small volume has rendered necessary the use of rather inconveniently small type. F. E. B.

Our Island-Continent: a Naturalist's Holiday in Australia. By Dr. J. E. Taylor, F.L.S. With Map. (London: S.P.C.K., 1886.)

DR. TAYLOR took a trip to Australia for his health, during which he visited South Australia, Victoria, and New South Wales. He has of course scarcely anything new to tell us, though his little book is pleasant reading, and many features of the island-continent are brought out that would only strike a naturalist. Why does Dr. Taylor not state the year of his visit?

The Handy Guide to Norway. By Thomas B. Willson, M.A. (London: Stanford, 1886.)

THIS is a business-like and compact guide which can easily be put into the tourist's pocket, though its price is rather surprising. This is probably due to the fact that it contains many sectional maps, an exceedingly useful feature to the intelligent traveller. The appendix on the Flora and Lepidoptera of Norway, by Dr. R. C. R. Jordan, will prove serviceable to the tourist interested in natural history.

Mountain Ascents in Westmoreland and Cumberland. By John Barrow, F.R.S. (London: Sampson Low and Co., 1886.)

MR. Barrow is an experienced Alpinist, but has a genuine appreciation of the gentler heights of his native land. He has ascended nearly every peak of any consequence in the Lake region, and this volume describes simply and clearly how he did it. The book will be useful as a guide to any who wish to follow Mr. Barrow's example; while the notes on the botany of the district render it of some scientific interest.

An Account of a West Indian Sanatorium, and a Guide to Barbados. By the Rev. J. H. Sutton Moxly. (London: Sampson Low and Co., 1886.)

THIS is a special plea for Barbados as a health resort, and Mr. Moxly adduces many facts in support of his position. The climate is superb, and the great drawback is want of drainage, giving rise to epidemics of typhoid fever. The book is well worth perusal by those in search of a winter-summer. The book will be useful as a guide, though we regret to note the absence of any map.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Fishermen's Foul Water

PERMIT me to call attention to the fact that the small gelatinous masses that annually, about this time, cause the sea-water to become what fishermen call "foul," are now in great abundance on this coast. Their recurrence this year being somewhat later than usual is doubtless owing to the low temperature of May.

On viewing a sample of the water in a glass vessel, the spherical and pyriform masses giving a brownish tinge are readily seen; and a pocket lens makes evident the presence of large specimens of the diatom *Eucampia britannica* that are seen as perfect spirals, some of which have four or five complete turns, and also some filamentous rods. Microscopic examination of the sediment deposited in the course of a few hours enables one to see *Rhizosolenia, Asterionella,* and several other diatoms whose names are not known to me.

Respecting the gelatinous bodies, I may remark that they are studded with granules that appear to be nucleated.

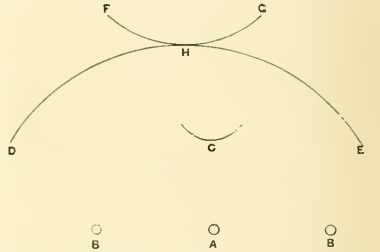
In one of these masses that I have had under observation to-day there has been a gradual segregration of the embedded germs, and this evening these exhibit individual movements which I think indicate the existence of cilia, although with a ¼-inch objective and C eye-piece (the highest power at hand) I cannot distinguish the cilia themselves.

It will be interesting to know how far round our shores at the present time these organisms extend, and I hope, by thus again directing attention to them, that some one more competent than myself will be led to investigate their life-history.

Sheerness W. H. SHRUBSOLE

Solar Halo

AT 6 p.m. this evening I observed an unusual halo and mock suns, a diagram of which is annexed.



A, the sun; B, B, mock suns; C, portion of halo, convex side towards sun; D E, portion of halo, concave side towards sun; F G, portion of halo touching D E at H. Distance—A to B, 22°; A to C, 22°; A to H, 44°.

The sky after having been overcast for the largest portion of the day was at this time fairly clear; very little lower cloud, but a good deal of cirrus. The measurements were observed with a sextant, and were exactly as given, reading the even degree in both cases. T. H. TIZARD

H.M.S. *Triton*, Great Yarmouth, June 21

Ampère's Rule

IN reviewing Mr. L. Cumming's "Electricity Treated Experimentally," "J. T. B." (NATURE, May 27, p. 74) humorously points out how easily students may get confused in trying to make use of "Ampère's rule." There is another rule, published by Pfaundler if I am not mistaken, which is in so far much simpler, as it does not compel the imagination to fancy movements and actions of the human body which it in reality never could perform:—

"Follow the direction of the current in moving the *right* hand along the wire, but holding it so that the stretched fingers are parallel to the wire and the palm is turned towards the north pole of the magnet. The outstretched thumb then gives the direction in which the north pole will be deflected."

Dresden-Striesen, June 12 G. DAEHNE

THE A.O.U. CODE AND CHECK-LIST OF AMERICAN BIRDS

SOME few years since the British Ornithologists' Union appointed a Committee to draw up and publish an authoritative list of the birds of the British Islands. This Committee consisted of the following English ornithologists:—P. L. Sclater (Chairman), Osbert Salvin, F. Du Cane Godman, Henry Seebohm, Howard Saunders, H. E. Dresser, R. Bowdler Sharpe, and H. T. Wharton (Secretary). The Committee held seventy-one meetings, and ultimately a list of British birds was published under the title "A List of British Birds, compiled by a Committee of the British Ornithologists' Union."

Notwithstanding the adverse criticism which has been passed on this little book by a few ornithologists, there can be no doubt that it has supplied a want, and that the high scientific position of many of the members of the Committee invested the publication with a degree of

authority worthy of the object of the work in question. Undoubtedly the "List" will bear improvement, and the second edition will perhaps contain not a few modifications, the constitution of the original Committee having necessarily embraced men holding different opinions on the subject of nomenclature and classification. Still, taking the results of their labours as a whole, it seems to us that the work was as well done as could have been expected, and was a well-meant attempt to introduce uniformity into the nomenclature of British birds.

But since the publication of the B.O.U. "List" a complication has arisen through the action of Mr. Henry Seebohm, whose work on British ornithology we have more than once alluded to in this journal. Mr. Seebohm makes short work of nomenclatural difficulties as far as British birds are concerned. Where any doubt arises respecting the oldest published name of a bird, or in cases when obscurity surrounds the meaning of an ancient description, Mr. Seebohm cuts the Gordian knot by taking the general consensus of opinion amongst ornithologists of repute, *i.e.* "*auctorum plurimorum*," and where he finds an actual majority of them have adopted a certain name, then he considers the latter to be the best known, and uses it accordingly. There is a decided advantage about this method. It simplifies matters amazingly, because in such cases as those of the Chiff-chaff, Garden-warbler, and many other familiar birds, the best-known names, *Phylloscopus rufus* and *Sylvia hortensis*, are restored to them, instead of *P. collybita* and *S. salicaria*, which Prof. Newton had shown them to be with more strictness entitled to. It is probable that had a few more years elapsed before Mr. Seebohm published his work, he would have had to modify his nomenclature even while adopting his *auctorum plurimorum* principle. For this reason. There is no ornithologist in this country more looked up to and respected than Prof. Newton, and with good cause. All his work is of the very best, and when he publishes anything, every ornithologist, whether approving his conclusions or not, knows that they are the result of the most careful and deliberate work, on which no time or labour has been spared, and be it an encyclopædia article or a complete work, the student may be sure that he will find the subject worked up in a way that will leave little for him to add. This is our experience of Prof. Newton's work, and it is work which will stand the test of time, for, as long as ornithology is studied, Prof. Newton's publications will always be found to carry the history of his subject down to the time in which he wrote, forming a starting-point for future study. Such being the position of the editor of the fourth edition of Yarrell's "British Birds," it is not surprising to find that his new edition of this standard work was received by ornithologists with respect, and that his nomenclature was at once adopted by the majority of the younger students in this country. Mr. Seebohm's synonymy of British birds shows this over and over again. Then the influence of Mr. Dresser's "Birds of Europe" cannot be under-rated, for he is content to sit at the feet of Prof. Newton, and unhesitatingly adopts his conclusions. Nor could he have done better, for the original work in the "Birds of Europe" is of the poorest quality, and it is as a successful and indefatigable compiler that Mr. Dresser is recognised, viewed in which light there can be no doubt that his work will be considered the work of reference on European ornithology for a long time to come. Thus we have the nomenclature of Prof. Newton, by its adoption in Mr. Dresser's standard work, doubly enforced on the ornithologists of Great Britain, and so followed by them that, as his synonymy shows, Mr. Seebohm would have found that in a few more years it would have been *auctorum plurimorum*, according to his own principles of nomenclature. Prof. Newton adheres faithfully to the rules of the British Association, and one knows, therefore, the principles by which he is guided. Mr. Seebohm differs on many questions from the Association Code, and we have our own ideas as to certain points of nomenclature, our protest being chiefly against men of the Bonapartian school, who take Linnean specific names and make them generic, adding a new specific name of their own. To our mind, Linnean names should be held sacred by zoologists, even if it involves the adoption of the subsequent genus, so that we must admit *Pica pica* or *Crex crex*. The question has been argued over before, and the usual verdict is against the adoption of this mode of nomenclature; but we have not found it unworkable in practice, and indeed it is often convenient, marking out the typical species of the genus. Sufficient has been said in the foregoing remarks to show that there is considerable variability of opinion even amongst British ornithologists with regard to the adaptability of the Association Code to the requirements of modern science.

But, between the method in vogue in England and that employed by American ornithologists, there has long been great divergence, increasing with years. We have all been looking for some authoritative, *and final*, work on the birds of North America, and it is with pleasure that we have lately received the "A.O.U. Code and Check-List of North American Birds," published by the American Ornithologists' Union. The Committee appointed for the purpose of drawing up this "List" was an excellent one, consisting of Prof. Elliott Coues, Messrs. J. A. Allen, R. Ridgway, W. Brewster, and H. W. Henshaw, while they also received the co-operation of Dr. L. Stejneger, who has made some notable researches into the synonymy of birds during recent years.

The "A.O.U. List of North American Birds" forms a bulky volume of nearly 400 pages. It is divided into five parts: an Introduction (pp. 1-17), in which a history of the subject is given, showing the various efforts of Committees and individual naturalists to systematise the treatment of scientific nomenclature. This is very completely done by the A.O.U. Committee, and with admirable fairness to the labours of their predecessors. Then comes the second section, propounding the "Principles, Canons, and Recommendations" (pp. 18-69), the "Check-List of North American Birds," according to the canons of nomenclature of the American Ornithologists' Union (pp. 71-347),[1] a "Hypothetical List" of recorded North American birds whose status is doubtful (pp. 349-357),[1] and, lastly, a most useful list of the "Fossil Birds of North America" (pp. 359-367).

The introduction calls for no remarks, but it is the "Principles and Canons" of the A.O.U. which will interest the British ornithologist.

In looking through the check-list and comparing the nomenclature used for some of the Palæarctic and Nearctic birds, the ordinary student will be somewhat startled. *Colymbus* is no longer to be retained for the Divers, but for the Grebes, and the Divers become *Urinator*, so that our ordinary Red-throated Diver, familiar as *Colymbus septentrionalis* is now *Urinator lumme*, of the American "List." From this it will be seen that the latter does not simplify existing nomenclature to begin with, and it is the great love of change, which has been so characteristic of recent ornithological work in America, which makes us sceptical as to whether even the authority of the A.O.U. "List" will be sufficient to prevent further modifications in this direction. We remember well how in our younger days we fell into the nomenclatural snare, and how we carried out, as we thought wisely, changes of well-known names in favour of one which had priority of a few years; and in one instance we remember rejecting a well-known name for another because the latter occurred a few pages earlier in the same book. These errors of judgment we have lived to repent, because we find with increasing experience that

[1] By some mistake the pages in the Table of Contents referring to these two sections are not correctly given (p. viii.).

the study of ornithology presents many phenomena of far deeper interest than the mere search after the oldest name, resulting, as it does too often, in the unearthing of some utterly unknown title, to the confusion of the student. The same principles of nomenclature which we tried to follow in earlier days are those of the A.O.U. now, which result in *Urinator lumme* as the name of the Red-throated Diver. And it is not as if there will be any finality about this nomenclature, for we have seen the treatment of too many monographs to make us believe this. When an ornithologist takes up a group of birds and monographs it, he spends months or even years of study on this particular group, obtains a grasp of his subject, and does his level best to give finality to his work. Does he succeed? Seldom, if ever. We hold it as an absolute canon that the nomenclature of monographs should be followed, unless a definite reason is given why a name should be altered. But, instead of this being done, we find, over and over again, that the author of a small paper or of a faunal list will, by altering generic names and so re-shuffling the specific names, give a totally different aspect to birds which have only just before been carefully monographed with a hope of finality in their nomenclature. So will it probably be with the A.O.U. "List," when some ornithologist in America will rise up and (as we expect to see before long) declare the trinomial system unworkable or the nomenclature of the "List" too complicated, and will re-shuffle the names, and attain temporary renown.

We think, however, that, now that the two leading Ornithological Societies of England and America have spoken with authority on the subject of the nomenclature of the birds of their respective countries, the British Ornithologists' Union should endeavour, if possible, to confer with the sister Society in America, and see if a common ground of agreement cannot be arrived at. If these two bodies came to a settlement, the whole matter could be laid before an Ornithological Congress, and there would be some hope of unanimity for the future. The points of divergence in practice between English and American ornithologists are less than might be supposed. The two principal ones are the adoption by the A.O.U. of the 10th edition of Linnæus's "Systema Naturæ" instead of the 12th edition, and the employment of trinomial nomenclature. So many English ornithologists are now using the latter mode that there ought to be no difficulty in conceding the latter point if any ornithologist like the method. Formulated as it is in the A.O.U. "Code," there is no difficulty in understanding what is meant by the trinomial titles, and the American Committee have given a clear definition of their object in Canon XI., though the difficulties which have been pointed out on this side of the water are still not disposed of. "In a word, intergradation is the touchstone of trinomialism. It is also obvious that, the larger the series of specimens handled, the more likely is intergradation between forms supposed to be distinct to be established, if it exists." So says the canon above quoted; but, we would ask, if two forms absolutely intergrade, why are they not of the same species? and why will not a binomial title be sufficient? and again, what name is to be given to the specimens collected at the point of contact? Or again, if a larger series of specimens proves that two species do not intergrade, as they were at first supposed to do, then they will each once more bear a separate specific name. Further, are trinomials to be used for insular forms, as is done by Mr. Allen for *Loxigilla noctis sclateri* from Santa Lucia, as there is no chance of intergradation between it and *L. noctis* from the neighbouring islands? Trinomial nomenclature has, however, taken such a place in American ornithology, and is adopted by so many naturalists in the Old World, that the principle must be conceded to all who like to avail themselves of it. The question with regard to the tenth edition of Linnæus's "Systema" might also be got over, but the A.O.U. will have greater difficulty in convincing European naturalists that it is advantageous to the progress of ornithological science to alter established nomenclature by introducing *Chelidon* as the generic name for the Chimney-swallow instead of the feather-legged Martins, which are to be henceforth *Hirundo*. This radical change is to be adopted in homage to Forster's "List of British Birds," a mere list of names without a character for a single genus. Although similar lists have sometimes been accepted for specific names, their recognition in the case of genera is rare, although in many instances long-established usage has rendered some of them familiar.

The few objections which we have made above must not be supposed to lessen our respect for the general tenour of the work now issued by our American *confrères*, whose labours deserve our most careful consideration, while it cannot be doubted that the publication of this "Code and Check-List" will have great influence on the future of zoological nomenclature.

R. BOWDLER SHARPE

PROFESSOR NEWCOMB'S DETERMINATION OF THE VELOCITY OF LIGHT[1]

THE method selected for the important experiments described in the present memoir,[2] is that known as Foucault's. The idea fundamental to it is that of the determination of the interval occupied by light in flashing from a revolving to a fixed mirror and back, by the amount of deviation produced in its return path through the change meantime effected in the position of the revolving mirror. The angle of deviation of the ray is double the angle of displacement of the reflector; to this angle corresponds (since the mirror rotates at a known rate) a definite fraction of a second, which is the time of luminous transmission across twice the measured distance between the mirrors.

But this theoretically simple means of ascertaining the velocity of light is complicated, in practice, with innumerable difficulties. A choice demanding the utmost nicety of judgment must be made between various conflicting conditions; sacrifice in one direction is the price of advantage in another; a balance has to be struck, giving the largest sum-total of facilities, with the fewest and least intractable drawbacks. The plan finally decided upon by Prof. Newcomb was the result of much anxious deliberation: we hope to render it, in its main outlines, intelligible to our readers.

A fundamental condition of the problem is to get an image of the light-source absolutely coincident with the light-source itself, *so long as the movable mirror is at rest*. And this, whatever be the position the mirror is at rest in, provided only that it be such as to permit the rays sent out by it to return, after due triple reflection, to the eye. This requisite is secured by locating the centre of curvature of the distant concave mirror in the axis of the revolving plane one. All rays emitted from this point towards the former will return along the same paths; differences of direction due to differing positions of the movable mirror will be eliminated by the return reflection; and there ensues a "stationary image" of the light-source, occupying, when visible at all, an invariable situation.

So far, all the operators by Foucault's method have been unanimous; but in the placing of the lens indispensable for the management and concentration of the light employed, a material distinction obtained between the

[1] "Measures of the Velocity of Light made under direction of the Secretary of the Navy during the years 1880–82," by Simon Newcomb, Professor, U.S. Navy. Astronomical Papers prepared for the use of the American Ephemeris and Nautical Almanac, vol. ii. parts iii. and iv. (Washington: Bureau of Navigation, 1885.)

[2] For the historical notice serving as an introduction to it, see NATURE, May 13, p. 29.

plan of experiment chosen by Prof. Newcomb, and that pursued by Prof. Michelson in his similar investigation at the Naval Academy in 1879 (see NATURE, vol. xxi. pp. 94, 120). Fig. 1 represents in principle the arrangement adopted by the former, which was also that used by Foucault. In it the lens, L, is placed between the light-source, S, and the revolving mirror, A. Fig. 2 shows the disposition preferred by Michelson, in which the lens is interposed between the revolving and fixed mirrors. In both equally, S and M are, and for the purpose in view necessarily must be, in conjugate foci of the lens.

A disadvantage of the first form is that the measurement of any considerable deviations will be attended by uncertainties caused by the oblique passage through the lens of the return beams. It was, however, obviated in the experiments under consideration, by the use of *two* lenses—one for the outgoing, the other for the incoming rays. The second method (Michelson's) promises increased brilliancy of the image; which may, nevertheless, be regarded as outweighed by atmospheric and other impediments to its distinctness, as well as by the illumination of the field of view produced by the passage through it of some part of the lens with every revolution of the mirror. The method exemplified in Fig. 1 was then chosen by Prof. Newcomb as affording more or less calculable conditions; while No. 2 involved all the uncertainties of definition habitually besetting astronomical observations.

Fig. 1.

Fig. 2.

Let us now endeavour to realise the nature of the experimenter's immediate task. The precise measurement of an angle actually constitutes it. From the mirror A, so long as it remains at rest, an image is reflected in a certain direction; but no sooner is A set rapidly rotating, than the same image is reflected in a slightly different direction. The amount of this difference—in other words, the angle of deviation—is the object to be ascertained.

Obviously, the first desideratum is to render the inevitable error of measurement comparatively small, by making the quantity to be measured large. Two roads are open towards this end. A high velocity can be given to the mirror A; or a great distance can be interposed between A and M. By the first means, the angle rotated through in a given time will be augmented; by the second, the time available for the displacement of the reflector will be prolonged by the lengthening of the journey imposed upon the rays to be reflected. The difficulties hampering increased speed are purely mechanical, though none the less formidable; those in the way of a lengthened path are optical.

The preservation of light enough to keep the image bright and distinct is of paramount necessity for the avoidance of ruinous uncertainties in its measurement. Now, in Foucault's experiments, the object affording the image was the line of a reticule. It was dark upon a bright ground; a platinum-wire relieved against a sheaf of sunbeams. But no perfectly defined image of such an object could be formed at any considerable distance; and we find, accordingly, that the utmost length by which he ventured to separate his mirrors was twenty metres. His entire apparatus was, in fact, contained in a single room. Hence, notwithstanding a speed given to his mirror of from 600 to 800 revolutions per second, the actual linear deflection of the return ray amounted to no more than seven-tenths of a millimetre. Chiefly by employing as his light-source an illuminated slit, the lucent image of which on a dark ground bore the enormous loss of light ensuing from the transportation of the fixed mirror to a distance of close upon 2000 metres, Michelson was enabled to augment this deflection some two-bundred-fold. The resulting velocity for light of 299,910 kilometres per second was proportionately trustworthy, the error of the angular measurement upon which it immediately depended being estimated to be one hundred times less than in Foucault's determination. Prof. Newcomb's improvements carried him still further towards absolute accuracy.

The details of construction of his "phototachometer" were decided on in the summer of 1879, and the instrument was completed by the Messrs. Clark in May 1880. It consisted essentially of four parts—a sending and a receiving telescope, a revolving and a fixed mirror. Sunlight, thrown from a heliostat through an adjustable vertical slit at the eye-end of the sender, passed down the tube, which was bent at right-angles to get it out of the way of the observing telescope, and after reflection by a plane mirror at the elbow, passed out through the objective towards the revolving mirror. This was formed by a

rectangular prism of polished steel, 85 millimetres in height, and with a cross-section of 37·5 square millimetres. The vertical faces constituting the reflecting area were nickel-plated, and proved of a remarkably durable though not very high polish. Motion in opposite directions at will was communicated by two air-turbines, acting one at the top, the other at the bottom of the mirror, and serving, by a simple contrivance, each for the regulation of the contrary velocity imparted by the other. A wheel-work arrangement, by which an electric current was broken once for every twenty-eight revolutions of the mirror, gave the means of obtaining a chronographic record of its rate of going. Two fixed mirrors, mounted side by side on cast-iron stands, were employed to return the light sent to them by the revolving mirror. Each was about 40 centimetres in diameter, and had a radius of curvature of some 3000 metres. The object-glass of the receiving telescope was (in the first instance) placed immediately under that of the sender, the former thus directly facing the lower, the latter the upper section of the movable mirror. The two *tubes*, however, owing to the "broken" form given, as already mentioned, to that of the sender, made with each other an angle of 90°. Horizontal movement round a vertical axis coincident with that of the rotating mirror, was possessed by the observing telescope, to which was attached a pair of microscopes for reading off the divisions on a horizontal divided arc fixed to a stiff frame at its further end. The amount of this horizontal motion of the telescope measured the deviation of the thrice-reflected sunbeam, and, by an immediate deduction, its velocity.

The site chosen for the erection of the apparatus was Fort Myer, on the south side of the Potomac, overlooking the city of Washington. The stationary mirrors, to and from which the carefully guarded rays performed their trips, were placed, to begin with, in the grounds of the Naval Observatory, at a distance of 2551 metres from Fort Myer; but were in 1881 removed to a point at the base of the Washington Monument, at a distance increased to 3721 metres. Some tentative experiments were undertaken on June 22, 1880; after a few days' trial, however, it was found that the wheel-work for counting the revolutions of the mirror was destroyed by the rapidity of the impressed movements. New wheels wore out almost before a set of readings could be obtained with them; until at length the Messrs. Clark, finding that no metal would stand the inflicted wear and tear, substituted *raw hide* as the material for the first wheel, a device which proved wholly successful. With the instrument thus modified work was begun on August 9, and continued without interruption until September 20. The transportation of the fixed mirrors to the Monument station in the spring of 1881 postponed the commencement of operations to August 8; and their effective prosecution was then impeded by the discovery of a source of systematic error in a "torsional vibration" of the rotating mirror. That is to say, the steel prism employed to reflect the light, no longer, when its speed attained a certain point, revolved as an absolutely rigid whole, but *tended towards* the possession of different velocities in its different parts. Hence a slight twisting of its mass producing vibrations round the axis of rotation, the effect of which was visible in the breaking up of the image of the slit into four separate images, one due to each of the faces of the prism. The persistence of this baffling symptom compelled a modification of the instrument, by which the sending and receiving telescopes could be respectively depressed and raised so as to alternate their positions, and the portions of the mirror they were directed towards. The mean of any two complete sets of observations made with the telescopes thus interchanged would be free, as Prof. Newcomb shows, from the effects of any probable form of torsional vibration.

No such effects, however, were apparent in the observations of 1882. This last series extended from July 24 to September 5, and were so nearly free from accidental differences that the probable error of a complete determination was scarcely more, under good conditions, than the ten-thousandth part of the whole. Upon these, accordingly, the chief reliance was placed in the final discussion of results.

The announcement that Messrs. Forbes and Young had detected a difference of 2 per cent. in the rates of transmission of red and blue light prompted, at Fort Myer, a most careful watch for traces of colour in the reflected image of the slit. But although, from a discrepancy of even one-twentieth that amount, a spectrum 15″ in breadth must have ensued, the iridescent edges which would infallibly have betrayed its presence were not seen.

An important novelty in Prof. Newcomb's method was his use of opposite rotations and their accompanying opposite deviations. In his instrument the mirror, as already stated, could be made to revolve at pleasure, either from right to left or from left to right. Instead, then, of measuring, as had always previously been done, the deflection produced in the return ray by the change from rest to an ascertained rate of rotation, the object of his determinations was the total deflection due to extremes

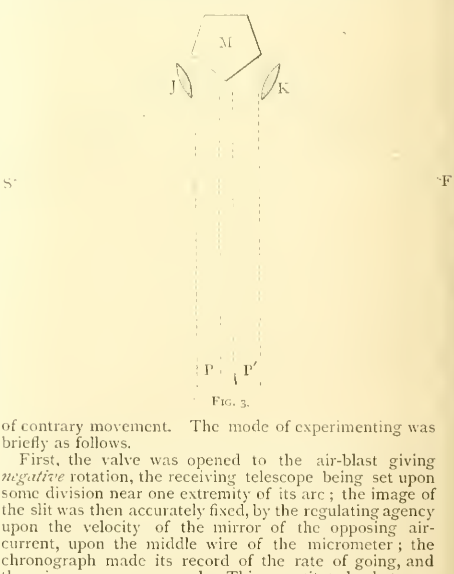


Fig. 3.

of contrary movement. The mode of experimenting was briefly as follows.

First, the valve was opened to the air-blast giving *negative* rotation, the receiving telescope being set upon some division near one extremity of its arc; the image of the slit was then accurately fixed, by the regulating agency upon the velocity of the mirror of the opposing air-current, upon the middle wire of the micrometer; the chronograph made its record of the rate of going, and the microscopes were read. This constituted what was called a "run," and occupied two minutes or upwards. The telescope was next unclamped, and directed near the opposite end of the divided arc. *Positive* motion was given by opening the other valve, and the process of fixing the image and reading off repeated. A comparison of the two sets sufficed to determine the time spent by the light in passing to and from the mirrors on the other shore of the Potomac.

This method of contrary deviations is most strongly recommended by Prof. Newcomb to future investigators. It combines the two advantages of doubling the angle to be measured, and of abolishing possible errors in the determination of the zero-point. In the present series, velocities, alternately in opposite directions, rarely ex-

ceeding 230 revolutions per second,[1] gave a total change of direction of nearly 8°. And this largeness of the measured angle materially contributed to enhance the accuracy of the results. Highly effective, also, for the same end were the elaborate precautions for darkening the telescopic field of view, and thus rendering the image of the illuminated slit more distinct. As their upshot, daylight was reduced to about one-thousandth its normal intensity. What was left only just sufficed to show the spider-lines without artificial light. The necessity for such precautions may be estimated from our author's statement that a concave mirror, of which the diameter should be one decimetre for each kilometre of distance, would receive only 1/60,000 part of the light reflected from the revolving mirror; while of that 60,000th part only a small fraction could be practically turned to account, owing to the many sources of loss in reflection and transmission. Since, however, *two* fixed mirrors, each four decimetres across, placed at a distance of less than four kilometres, were employed in the operations at Fort Myer, the proportion of light there returned was rather more than double the above estimate. Prof. Newcomb appears to have been, on the whole, eminently successful in his optical arrangements. The imperfect definition which was the besetting difficulty of Michelson's experiments gave him little trouble.

The recent American determinations of the velocity of light, justly considered as of far superior precision to any others yet executed, give the following results:—

Michelson, at Naval Academy, in 1879	299,910 km.
Michelson, at Cleveland, 1882	299,853 „
Newcomb, at Washington, 1882, using only results supposed to be nearly free from constant errors	299,860 „
Newcomb, including all determinations	299,810 „

To these are added for comparison:—

Foucault, at Paris, in 1862	298,000 „
Cornu, at Paris, in 1874	298,500 „
Cornu, at Paris, in 1878	300,400 „
The same, discussed by Listing	299,990 „
Young and Forbes, 1880-81	301,382 „

Prof. Newcomb's finally-concluded result is that light travels *in vacuo* at the rate of $299,860 \pm 30$ kilometres per second. And the probable error of thirty kilometres, small as it is, has been liberally estimated. A determination so satisfactory of this important element goes far towards solving the problem of the sun's distance. Combined with Nyrén's constant of aberration, 20″·492, it gives, for the solar parallax, the value of 8″·794. The corresponding distance of 149·61 million kilometres, or 92,965,020 miles, agrees quite closely with Dr. Gill's result from the opposition of Mars in 1877, and exceeds by only 165,020 miles the mean deduced by Mr. D. P. Todd from earlier determinations of light-velocity. No information as to the dimensions of the solar system which we are ever likely to get from a transit of Venus can approach in reliability the present conclusion.

Prof. Newcomb is so far from believing that the *ne plus ultra* of accuracy has been reached in his own remarkable experiments, that he appends to the detailed description of their method some valuable suggestions for its improvement. He had hoped, indeed, he tells us, to reach a concluded value exact to between five and ten kilometres, which, after repeated verification, might be available as a test of the invariability of standards of length. The further prosecution of the inquiry, however, he now leaves to any physicist who may be invited to the task by the promise of his advice and co-operation.

Fundamentally, he holds that the system pursued at Fort Myer in 1880-82 is preferable to any other yet tried. No known expedient for ascertaining the rate of transmission of light is comparable to that of its deflection, after a measured journey, by a moving mirror. The apparatus by which this plan was realised admits, however, in his opinion, of some amelioration in detail. The disadvantageous necessity, for instance, of appropriating a separate section of the reflecting surface to the outward- and homeward-bound rays could be removed by the substitution of a pentagonal for a quadrangular prism, as shown in Fig. 3, where M is a section of the revolving mirror, J the object-glass of the sender, receiving light from the slit S, and throwing it in the direction P towards the distant reflector. On its return along the path P′, the ray is reflected from an adjoining face of the revolving mirror into the receiving telescope, K.

[1] Michelson's revolving mirror executed 256 turns in a second.

The closing words of the paper under review attest the unappeased aspiration towards accuracy characteristic of the successful investigator.

"A still further perfection of the method," its author writes, "which would lead to a result of which the precision would be limited only by our means of linear measurement is, I conceive, within the power of art. It consists in placing the fixed mirror at so great a distance that the pentagonal revolving mirror would move through an arc of nearly 36° while the ray is going and returning. If a speed of 500 turns per second could be attained, the required distance would be thirty kilometres. Then, in opposite directions of rotation, the return ray would be reflected at phases of the mirror differing by the angle between two consecutive faces. The result would be that the receiving telescope would need to have but a small motion, and all the observer would have to measure would be the small angle by which the difference of positions of the mirror when the flash was received in opposite directions of rotation, differed from 72°. In the Rocky Mountains or the Sierra Nevada no difficulty would be found in finding stations at which a return ray could be received from a distance of thirty, forty, or even fifty kilometres, with little more dispersion and loss than at a distance of four kilometres through the air of less favoured regions. It is true that the surface of the distant reflector would have to be increased in proportion to the distance, but it would not be necessary to make a single reflector of great size. A row of ten reflectors, each six or eight decimetres in diameter, might be sufficient to insure the visibility of the return ray."

A. M. CLERKE

NOTES

AT a meeting of the Royal Society of Edinburgh on June 7, medals were presented as follows:—To Mr. John Aitken (Darroch), the Keith Prize for 1883–85, for his paper on the formation of small clear spaces in dusty air, and for previous papers on atmospheric phenomena; to Edward Sang, LL.D., the Makdougall-Brisbane Prize for 1882–84, for his communication on the need for decimal subdivisions in astronomy and navigation and on tables requisite therefor, and generally for his recalculation of logarithms both of numbers and of trigonometrical ratios; to Mr. B. N. Peach the Neill Prize for 1883–86, for his contributions to the geology and palæontology o Scotland.

THE organising committee of Section A has arranged that a special discussion shall be held, at the Birmingham meeting of the British Association, jointly with Section D, on the physical and physiological theories of colour-vision. The discussion will be opened by Lord Rayleigh, and Dr. Michael Foster will also take part in it. Persons who wish to contribute papers bearing on the subject of discussion are requested to send their names to the Recorders of Sections A or D, at 22, Albemarle Street, W., not later than August 1.

THE death is announced, in his seventieth year, of Mr. Llewellyn Jowett, the well-known archæologist.

At the Conference at the Colonial and Indian Exhibition on Wednesday, June 23, a paper was read by Mr. W. Lant Carpenter, on "The Position of Science in Colonial Education." The colonies to which Mr. Carpenter had directed his attention were:—Canada generally; South Africa, the Cape of Good Hope and Natal; Western and South Australia, Victoria, New South Wales, Queensland, New Zealand, and Tasmania, the last of which, unfortunately, is not represented at the present Exhibition. An account of the present condition of scientific education in each of these colonies was given. As a general conclusion, Mr. Carpenter thought that the claims of science to a place in State-aided primary education were more fully recognised than in the old country, and this, not merely because it was the only foundation upon which a system of technological education could be securely built, but for its value in drawing out the minds of the pupils. As regards the branches by which the time-honoured routine of subjects may be most beneficially varied, precedence was almost universally accorded to drawing, and to the objective presentation of the elements of science. In secondary grammar and high schools, however, science scarcely occupied a position equal to that in corresponding English schools, but there were many signs of improvement in this respect. In the Colleges and Universities of the older colonies the classical and academic influence was still very strong, while in the newer ones the claims of scientific education to be put on an equal footing with literary were recognised. Great has had been the progress of public opinion in England during the last few years on the importance of science as an element in education, the author was disposed to consider it greater in the colonies in the same period. Certainly the development of that opinion to its present point had been much more rapid in the colonies than at home. There were many voluntary colonial Associations for the promotion of science, and the author concluded his paper by throwing out the suggestion that, if there were grave and practical difficulties in the way of an Imperial federation of the Australian colonies, the establishment of an Australian Association for the Advancement of Science, somewhat on the lines of the British and American Associations for similar purposes, might not be beyond the reach of practical men of science, and he was strongly of opinion that such a federation would tend to strengthen "the position of science in colonial education."

Arrangements have been made for the examination in the Indian Court of the Colonial and Indian Exhibition of certain commercial products, which are believed to be insufficiently known or to be suitable for new purposes. Among the substances which will be examined are fibres, silk and silk substitutes, drugs, tobacco, gums and resins, minerals, oils, oil-seeds and perfumery, dyes, mordants and pigments, timbers, tanning materials and leather, and food-stuffs. Any visitors to the Exhibition, who are interested in the subject, will be permitted to attend these examinations of products, which will take place in the Commercial Room, attached to the Economic Court, where all further information may be obtained. Should the results of this examination render such a course desirable, Conferences of a formal character will probably be held at a later date.

The International Society of Electricians has decided upon building laboratories for the use of physicists in Paris. They will be established in the grounds of the old Collège Rollin, granted by the city of Paris, in the vicinity of the School of Practical Physics recently erected by the Municipal Council. The funds will be supplied by public subscription, a contribution from the Society, and a sum of 360,000 francs, which is the surplus of the last Electrical Exhibition organised by M. Cochery.

We take the following from *Science*:—It will be remembered that in the month of May a gentleman in Brooklyn died from hydrophobia. His medical attendants, competent physicians, had no doubt about their diagnosis, and his symptoms were characteristic of that disease. Confirmatory of this opinion, the autopsy revealed no lesion to which could be attributed the symptoms from which he suffered—a condition which is also characteristic of hydrophobia. Portions of the brain and the spinal cord were carefully wrapped in cloth wet with a solution of bichloride of mercury and sent to Dr. Sternberg. Small portions of these were thoroughly mixed with sterilised bouillon; and this broth was then, by means of a hypodermic syringe, injected under the dura mater covering the brain of a rabbit, a small button of bone having been first removed by a trephine. The wound was then closed by sutures. Three rabbits were thus operated upon. One died at the end of twenty-four hours as the result of the operation; hydrophobia, of course, having nothing to do with it. Another is now, after eighteen days, apparently well. The third one, on the sixteenth day, commenced to show signs of being ill: he was disinclined to move, and in a few hours evidences of paralysis appeared, at first in the hind-legs, and subsequently in all the extremities. On June 5, the eighteenth day after the operation, he died. The wound had healed, and there were no evidences of inflammation. The brain showed no softening at the point where the inoculation was made, no pus, nor any evidences of inflammation either of the brain substance or of its membranes. The cord also appeared normal. Portions of the medulla of this rabbit were immediately mixed with sterilised bouillon, and two rabbits were inoculated in the same manner as has been described. This case is of great interest as being, so far as we know, the first animal in this country to become affected with hydrophobia from inoculation with material taken from a person who died from that disease. If Dr. Sternberg is as successful with these rabbits as with the first, there is no reason why the series cannot be continued, and thus the protective virus of Pasteur be obtained in this country, and a trip to Paris by the victims of dog-bites made unnecessary. As we go to press we learn that the second rabbit, mentioned above as remaining unaffected for eighteen days, shows unmistakable signs of hydrophobia.

Dr. Thornton, the new Director of the Madras Museum, has organised a series of investigations for the purpose of studying systematically the marine and terrestrial fauna on the west coast of the Presidency. They will be continued from time to time as favourable opportunities arise.

At 8.40 a.m. on May 17 a remarkable phenomenon was witnessed at Dönnæs, in the north of Norway, some twenty five miles south of the Polar Circle. A small bright horizontally-lying circle was suddenly seen with its centre right in zenith, the periphery passing through the centre of the sun. In the circle were besides four mock suns, in east, west, north, and south, so that they would almost have formed the corners in an irregular square. There was also another circle perpendicular on the other, and with the sun as centre, but it was much fainter. The little circle and the two mock suns nearest the sun were rainbow-coloured, and the great circle and the two mock suns furthest off intense white. After half an hour the phenomenon faded for a while, but soon again became as intense as before. It disappeared after having been in view for an hour and a half. The weather was fine and sunny, but hazy. Afterwards it became cloudy with rain.

The large zoological collection known as the Museum Godeffroy has just been purchased by Mr. Damon (Weymouth). The ethnological portion was sold a short time since to the Leipzig Museum, as already announced in Nature.

In addition to the specially meteorological results contained in the report of the Hong Kong Observatory for the past year,

which we noticed last week, Dr. Doberck, the Government Astronomer there, refers to the great value of the systematic meteorological observations with verified instruments which have lately been set on foot at many of the stations and lighthouses of the Chinese Customs, and which will serve as an important aid in the investigation of typhoons. He pays a well-deserved tribute to Japan's "extensive meteorological service, conducted on approved principles," and to the useful weather maps issued by the Tokio Observatory, while he deplores the absence of a similar comprehensive service in the Philippines and the non-publication of such data as are observed there—an omission which increases the labour of following typhoons in their passage across or near to those islands. The intention of the French authorities to establish a meteorological observatory at Haiphong, on the coast of Tonquin, seems to have been dropped, at least for a time, since the death of the distinguished meteorologist, Dr. Borius. The Hong Kong Observatory during the year was supplied with a gazing-telescope, as was recommended by Col. Palmer in the original project, a Lee equatorial from Greenwich having been erected. In 1882, when the plan of the Hong Kong Observatory was first drawn up, the local Government was willing to pay for one thoroughly equipped, but the Colonial Office at home cut out the most important part of the provision for magnetic research, and this unfortunate spirit of parsimony in expenditure connected with scientific research seems now to have extended to Hong Kong. For Dr. Doberck complains that the addition to the work of his Observatory is not accompanied by a corresponding increase of funds and staff, that his telegraphic facilities are insufficient to give full effect to the proper purposes of the establishment, that the slopes of the observatory hill have been left unturfed since they were stripped in 1883, and that no effective measures have been taken to improve the unhealthiness of the site, which is on the Kowloon peninsula opposite the town of Victoria. It sounds incredible that the gun which was supposed to be set apart for the purpose of announcing the approach of a typhoon has also been used to announce the arrival of the mail-steamers—a course which is as senseless as it is cruel, for it confuses the unfortunate boat- and junk-men who swarm in the Hong Kong waters, and who either throw up their work and flee into a place of refuge when only a mail-steamer is arriving, to their great loss of time and money, or they take no precautions at all when a typhoon is really at hand. In the latter case, if any lives were lost, an English coroner's jury would probably indict the official responsible for this gross negligence for manslaughter, as they would the chemist who carelessly gives strychnine in place of Epsom salts. Dr. Doberck proposes that, if the gun be used for post-office purposes, it should cease altogether as a typhoon warning.

AT the annual meeting of the Chemical Society of Tokio, held on April 10, and reported in the *Japan Mail*, a very satisfactory report was read. The Society is composed of Japanese and foreign men of science, the total number of members last year being eighty-six, and being constantly on the increase. The number of papers read amounted to nineteen. The journal of the Society is published four times a year, and it is hoped to make it a monthly journal soon, "especially as the number of papers read is not few, nor their nature inferior to those which appear in foreign journals." The Society undertook to translate chemical terms into Japanese about four years ago, and it now possesses (though not yet published) a dictionary of commoner chemical terms in Japanese, English, French, and German. It has also undertaken to establish a system of chemical nomenclature in the Japanese language, of which the nomenclature of the elements and of inorganic compounds is already nearly finished. It is hoped that a sound and complete system of nomenclature will be published in the course of the coming year. An address was delivered by Mr. Watanabe, the head of the new University of Japan, and, on other grounds, an important official, who impressed on the members of the Society the necessity of making chemistry popular, on account of its intimate connection with arts and manufactures. He hoped, too, that more and more original work in science would be done in Japan, for on such work depended ultimately all improvement in manufacturing processes.

AT the same meeting a paper was read by Dr. Kellner on the deportment of urea towards soils, with special reference to the mode of manuring the soil employed in China and Japan. The experiments on this subject which have been carried out at the Komaba Agricultural College show that the application of fresh excreta is injurious to crops, and that, in this state, a great deal of the most valuable nitrogenous compounds of the manure is lost by rain, which carries the urea into the deep subsoil beyond the reach of the roots of the plants. Japanese farmers had long ago come to a similar conclusion for themselves, for they only employed this manure when in a highly decomposed state, when the urea had been converted by putrefaction into ammonium carbonate.

THE report of the Rugby School Natural History Society for the past year is a very satisfactory one, for it shows great activity on the part of the members and of the Society collectively in every direction. With a single exception the papers are contributed by working members or associates; the collection of British quadrupeds commenced last year is almost complete, and a new vivarium has been added to the Society's resources. The papers deal with many subjects from China to heraldry, but local ornithology appears to have received special attention; for the Society's first prize essay was won by Mr. Austen with a paper on the water-birds of Rugby; the second by Mr. Mander, on some of the large birds round Rugby. Mr. Solly also contributes an interesting paper on microscopic fungi, with illustrations. But it is in the sectional reports that the activity of the Society is made most manifest. Here we find a meteorological report, based on continuous observation throughout the year; a vivarium report; a report from the entomological section, containing a list of the Lepidoptera observed at or near Rugby during the year; similarly the report of the botanical section contains a long list of observations, in which are some plants hitherto unknown in the flora of Rugby; the zoological report, it may be added, is a specially long one; and the book concludes with the report of the Temple Observatory, where so much good astronomical work is being done. Of the many excellent natural history societies which pass under our notice from time to time, few can show more or better work than the Rugby School Society.

ONE interesting matter referred to in the report just noticed was the presentation of an address of congratulation to Mr. M. H. Bloxam, a very energetic member of the Society, on reaching his eightieth year. In his reply Mr. Bloxam claimed to be, in a peculiar degree, a link between the Rugby of the present and that of the past. He transacted business with a Rugbeian who entered the school in the reign of George II., 127 years ago. Mr. Bloxam entered Rugby School about 72 years ago, and left it 64 years ago; and while he was at the school a retired master died who was born in 1718, early in the reign of George I., 167 years ago. The Rev Henry Holyoak was master of the school in the boyhood of that retired old master, and Mr. Holyoak was alive in the lifetime of a nephew of Lawrence Sheriff, the founder of Rugby School. Now Lawrence Sheriff died 318 years ago. Thus three lives, one of them being Mr. Bloxam's, carry us back to the foundation of Rugby School.

We are requested to state that the annual Students' *Conversazione* will take place at the Finsbury Technical College on Friday evening, July 2, commencing at 7 o'clock. A good exhibition of apparatus, models, and specimens has been arranged to illustrate the various branches of applied science and art comprised under the College scheme of technical education.

A Swedish geologist, Dr. H. Sjögren, is about to proceed to the naphtha regions on the Caspian Sea, in order to prosecute geological studies.

We have received from Messrs. Griffin and Co. the third annual issue of the "Year-Book of the Scientific and Learned Societies." It gives a brief chronicle of the work done during the year by the various Societies, together with the necessary information as to official changes.

The Saghalien Ainos do not exhibit the same uncouthness as those of Yezo; there is a greater absence of beards and of hairy bodies generally. The hue of the skin very closely resembles that of the Caucasian; the foreheads are high but narrow, and their general bearing and facial expression denote an intelligence much superior to that of the Yezoines. As for the theory of an ethnical connection between the Ainos and the Japanese, Mr. Penhallow says that an examination of the pure types would not permit such a belief to be entertained. There is a mixture of the two in places, but the half-breed is as easily recognisable there as elsewhere in the world. The Japanese, he concludes, are unquestionably Mongoloid, while the facts show the Ainos to be physically distinct, while the best authorities agree in the great resemblance which they bear to Europeans, the prevailing view being that they are distinctly Aryan.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Mrs. George Willing; two Tcheli Monkeys (*Macacus tcheliensis* ♂ ♀) from Jung-ling, near Pekin, presented by Dr. S. W. Bushell, C.M.Z.S.; a Wild Swine (*Sus scrofa* ♀) from Tangier, presented by Mr. John Brooks; four Sparrow Hawks (*Accipiter nisus*), British, presented by Mr. J. Rowland Ward, F.Z.S.; an Egyptian Goose (*Chenalopex ægyptiaca*), a Robben-Island Snake (*Coronella phocarum*), a Hoary Snake (*Coronella cana*), an Infernal Snake (*Boodon infernalis*), a Rhomb-marked Snake (*Psammophylax rhombeatus*), a Horned Viper (*Vipera cornuta*), eight Geometric Tortoises (*Testudo geometrica*), a Leopard Tortoise (*Testudo pardalis*), three Areolated Tortoises (*Homopus areolatus*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Crowned Horned Lizard (*Phrynosoma coronatum*) from California, presented by Mr. S. Upton Robins; a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain; a Tuatera Lizard (*Sphenodon punctatus*) from New Zealand, presented by Capt. R. Sutherland; a Tarantula Spider (*Mygale*, sp. inc.) from Bahamas, presented by Mrs. E. Blake; a Peruvian Thicknee (*Œdicnemus superciliaris*) from Peru, two White-backed Piping Crows (*Gymnorhina leuconota*) from Australia, deposited; a Balearic Crane (*Balearica pavonina*) from West Africa, purchased; a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

The Absorption Spectrum of Oxygen.—About three years ago M. Egoroff was able to show that the great groups A and B in the solar spectrum were due to the absorption of oxygen. More recently the α band was also found to be due to the same gas. M. Janssen, studying the absorption of oxygen has now discovered that under certain conditions the gas yields another spectrum, composed no longer of lines easily separated, but of shaded bands which can only be resolved with great difficulty. This system of bands appears for moderate pressures much later than the spectrum of lines, but it shows itself very quickly with increase of the density: the two systems are so different that it is possible to obtain either the first without the second or *vice versâ*. M. Janssen was at first unable to explain how it was that these bands were not visible in the solar spectrum when they were easily obtained by passing light through thicknesses of oxygen far less than the sun's light has to traverse before reaching us. But further experiments showed that these bands did not develop in proportion to the thickness of the stratum of oxygen producing them, multiplied by its density, but in proportion to the thickness multiplied by the square of the density. The density of our atmosphere being small as compared with some of the pressures at which M. Janssen worked, the non-appearance of these bands amongst the telluric lines of the solar spectrum is readily explained.

Potsdam Observatory.—The fifth volume of the *Publications* of the Astrophysical Observatory of Potsdam is occupied with a very careful determination, by Drs. Müller and Kempf, of the wave-lengths of 300 of the principal lines in the solar spectrum. Four gratings were used in this inquiry—one with about 2500 lines to the inch, the second with 6250 lines, and the third and fourth with about 10,000 lines to the inch. Eleven normal lines were first measured with all four gratings and in the spectra of three or four orders with each grating, every observation being carefully corrected for temperature, &c. The computation of the wave-lengths of the 300 lines follows, and the details of the reduction of the observations of the eleven normal lines, and a catalogue of the wave lengths of 2614 lines as given in the Potsdam Atlas of the spectrum, and as now corrected, concludes the work. The following are the wave-lengths of the selected normal lines, expressed in millionths of a millimetre:—C, 656·314, 640·035, 612·247; D_2, 589·625, 562·475, 545·580; b_2, 517·284, 495·770, 470·321, 441·534, and 407·186. It would seem from these determinations that Angström's wave-lengths require small but sensible corrections.

The Binary Star γ Coronæ Australis.—With reference to our note on this double star (Nature, vol. xxxiii. p. 425), in which we pointed out the large difference in the position-angles computed, for the present year, from the orbit of Mr. Gore and from that of Mr. Downing, we may draw attention to a communication by Mr. H. C. Wilson, of the Cincinnati Observatory, printed in the *Observatory*, No. 111, pp. 234–235. Mr. Wilson gives the mean results of observations of the binary in 1881 and 1883 as follows:—

1881·72	45°·53	1″·38
1883·62	37·75	1·62

The angles computed from Mr. Gore's elements for these two epochs are respectively 47°·29 and 36°·49, which may be regarded as agreeing fairly well with the observations. It appears, therefore, that of the two orbits referred to above, Mr. Gore's is by far the most satisfactory.

Observations of the Companion of Sirius.—Prof. Young has communicated to the *Sidereal Messenger* (No. 46, p. 182) a series of measures of the companion of Sirius made at Princeton, for the most part with the 23-inch refractor, with powers of 460 and 300. Prof. Young remarks that during the present year the companion has been a difficult object, except when the seeing was good, and there have been fewer good nights than usual. The mean annual results are:—

Position-Angle			Distance		
Epoch	Measure	No. of nights	Epoch	Measure	No. of nights
1883·105 ...	39°·0 ...	1 ...	1883·105 ...	9″·41 ...	1
1884·273 ...	36·30 ...	5 ...	1884·270 ...	8·70 ...	4
1885·112 ...	34·06 ...	7 ...	1885·089 ...	8·09 ...	8
1886·047 ...	29·77 ...	4 ...	1886·049 ...	7·59 ...	3

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 JUNE 27—JULY 3

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 27

Sun rises, 3h. 47m.; souths, 12h. 2m. 44·1s.; sets, 20h. 19m.; decl. on meridian, 23° 20′ N.: Sidereal Time at Sunset, 14h. 42m.

Moon (three days after Last Quarter) rises, 1h. 6m.; souths, 7h. 59m.; sets, 15h. 4m.; decl. on meridian, 9° 31′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury ...	5 1	13 17	21 33	23 25 N.
Venus ...	1 42	9 18	16 54	17 22 N.
Mars ...	11 20	17 30	23 40	1 11 N.
Jupiter...	11 17	17 31	23 45	2 3 N.
Saturn ..	4 16	12 26	20 36	22 34 N.

June	h.	
28 ...	10	.. Mars in conjunction with and 0° 59′ south of Jupiter.
29 ...	0	... Venus in conjunction with and 2° 57′ north of the Moon.
July		
2 ...	16	... Sun at greatest distance from the Earth.

SECOND ANNUAL REPORT OF THE COUNCIL OF THE MARINE BIOLOGICAL ASSOCIATION OF THE UNITED KINGDOM[1]

I. THE Council has met during the past year nine times, viz. on October 5, October 27, December 14, March 19, March 25, April 5, April 9, May 19, and June 7. The chief business which has occupied the Council during the past year has been the preparation of the plan of the Laboratory building now in course of erection on the Citadel Hill at Plymouth, and the arranging for the execution of this plan by building and engineering firms. Further, the Council has given much time and attention to negotiations with the Lords of Her Majesty's Treasury with regard to a grant in aid of the objects of the Association.

The most important facts which the Council has to communicate to the Association as the result of the year's work are:—

(1) The undertaking on the part of the Lords of the Treasury to submit to Parliament a grant of 5000*l.*, to be paid in two yearly instalments, and 500*l.* a year for five years, in aid of the objects of the Association; and

(2) The formal approval by the Council of a contract by Mr. Berry, of Plymouth, to erect the buildings and construct the reservoir of the Plymouth Laboratory at the price of 5902*l.* 16*s.*, and also of a contract by Messrs. Leete, Edwards, and Norman, of London, to construct and fit the aquariums and pumping apparatus for the Plymouth Laboratory at the price of 3000*l.*

The excavation of the site on the Citadel Hill at Plymouth is now actually in progress, and the Laboratory will be in all probability ready for occupation by this time next year.

In June 1885, the Council reported a capital sum of nearly 8000*l.* as definitely promised to the Association, of which 4787*l.* was in the hands of the Treasurer.

The Council now has to report a capital sum of 10,000*l.* available for expenditure on the building and fitting of the Plymouth Laboratory, and in addition an annual income from investments and annual subscriptions of 1100*l.* a year. Of the disposable capital sum about 5000*l.* is in the hands of the Treasurer, whilst the sum of 5000*l.* is to be paid in two instalments, one in 1886, and one in 1887, by Her Majesty's Treasury.

In June 1885, the Association numbered 277 members, of whom 163 were annual subscribers, the rest having compounded. It now numbers 305 members, of whom 169 are annual subscribers.

Amongst important donations to the Association made during the past year, the Council desire especially to mention the sum of 500*l.* received from Mr. John Bayly, of Plymouth, who was already a Founder, and is now qualified as a Life Governor of the Association. On hearing that the Council felt it to be necessary to omit certain features in the plan of the Plymouth Laboratory as approved by them, on account of the expense involved, Mr. John Bayly came forward with this munificent donation, and thus enabled the Council to carry out their original design.

II. In reference to the grant from the Treasury, the Council submit, for the information of the members of the Association, the final letter received from the Lords of the Treasury and the answer returned by the Council to that communication.

Treasury Chambers, December 9, 1885

SIR,—I have laid before the Lords Commissioners of Her Majesty's Treasury your letters of the 2nd and 13th ultimo, on the question of the proposed assistance to be given by the Government to the Marine Biological Association of the United Kingdom. Their Lordships have considered the matter very carefully, and they now desire me to inform you that they are prepared to propose to Parliament a grant of 5000*l.* towards the cost of the Laboratory which the Association intends to construct at Plymouth, such grant to be paid in two instalments of 2500*l.* each, one in 1886 87, and the other in 1887–88, and also an annual grant of 500*l.* for five years, beginning in the year 1887–88, towards the current expenses of the Laboratory, on the following conditions:—

(1) That the Council of the Association agrees to have its accounts formally audited each year, and to furnish a statement of income and expenditure to the Treasury.

(2) That the Council undertakes to issue at regular intervals (probably half-yearly) a detailed report of the work done in the Plymouth Laboratory, and to furnish the Treasury with such report.

(3) That the Council pledges itself definitely to aim at procuring practical results with regard to the breeding and management of food-fishes.

(4) That the Council undertakes to place space in the Plymouth Laboratory at the disposal of any competent investigator deputed by a recognised authority to carry out any investigation into fish questions for which the Laboratory can give facilities.

I am to add that my Lords will make the necessary provision for these grants in the Estimates for the coming year, but until Parliament shall have sanctioned the grant, it will not be in their power to make any payments to the Association in fulfilment of the above promise of assistance.

In conclusion I am to suggest, with reference to your letter of the 8th instant, that in future any communications between the Association and the Scotch Fishery Board should be conducted through the Secretary for Scotland.

I have the honour to be, Sir, your obedient servant,

M. W. RIDLEY

[1] Presented to the Annual General Meeting of the Association on June 8, 1886, Prof. Huxley, President of the Association, in the chair.

SIR,—I have laid before the Council of the Marine Biological Association your letter of the 7th inst., and I am instructed by the Council to say that they accept the four conditions mentioned in your letter as those upon which the Lords Commissioners of Her Majesty's Treasury are prepared to propose to Parliament a grant of 5000*l*., and an annual grant of 500*l*. a year for five years, in aid of the building and of the current expenses of the Laboratory about to be erected by the Association on Plymouth Sound.

The Council of the Association desire me to express, through you, to my Lords, the gratification which they experience in receiving this important assistance and mark of confidence from my Lords, and to offer at the same time their thanks to my Lords for the favourable consideration which has been accorded to the request of the Council.

In regard to the term "a recognised authority" used in the fourth condition proposed by my Lords and accepted by the Council, I am directed to say that the Council assumes that a "recognised" authority means a "STATE" recognised authority, such as the Scotch Fishery Board or Her Majesty's Inspectors of Fisheries.

On behalf of the Council of the Marine Biological Association I am accordingly empowered to state—

(1) That the Council agrees to have its accounts formally audited each year, and to furnish a statement of income and expenditure to the Treasury.

(2) That the Council undertakes to issue at regular intervals (probably half-yearly) a detailed report of the work done in the Plymouth Laboratory, and to furnish the Treasury with such report.

(3) That the Council pledges itself definitely to aim at procuring practical results with regard to the breeding and management of food-fishes.

(4) That the Council undertakes to place space in the Plymouth Laboratory at the disposal of any competent investigator deputed by a recognised authority to carry out any investigation into fish questions for which the Laboratory can give facilities.

I have the honour to be, Sir, your obedient servant,
E. RAY LANKESTER, Hon. Sec. M.B.A.
To Sir M. W. Ridley, Bart.

III. The attention of the Council having been drawn to the statement made in the House of Commons by the President of the Board of Trade to the effect that it was the intention of the Government to constitute a Fisheries Department under that Board, the following letter was addressed on March 19 to the President of the Board of Trade :—

April 7, 1886

SIR,—I am desired by the Council of the Marine Biological Association to inform you that they have observed from an official statement in Parliament that it is the intention of Her Majesty's Government to constitute a Fishery Department as a branch of the Board of Trade. With a view to the meeting of the Council of the Association on March 19 last, I took the liberty to inquire whether you would be disposed to receive a deputation from the Council in order that it might have an opportunity of placing before you some account of the origin of the Association and of its proposed operations with regard to the fisheries of the British seas. The Council having learned that you thought the reception of such a deputation inadvisable, have instructed me to communicate to you, in accordance with your invitation, a brief account of the position of the Association and of its relations to the Government.

The Council have taken steps to erect on the Citadel Hill, at Plymouth, on a site granted by the War Office, a Laboratory, which will be equipped with all the appliances in the shape of tanks and working rooms suited for the study and observation of fishes and other marine organisms. It will afford convenient accommodation for from sixteen to twenty scientific investigators qualified to engage in biological research.

In view of the national utility of such a Laboratory in connection with the fishing industry, the Lords Commissioners of Her Majesty's Treasury have agreed to submit to Parliament a vote of 5000*l*., in two annual instalments, towards the erection of the Laboratory, and to supplement this when the Laboratory has been completed by an annual subsidy of 500*l*.

I am directed to annex for your information a copy of the letter from my Lords embodying these undertakings. You will observe that they have laid stress on the duty of the Association to investigate everything relating to the economy of food fishes, and that they further desired that the Marine Biological Association should work in harmony with the Scotch Fishery Board, which was, at that time, the only formally constituted body connected with the subject in Great Britain.

The Council apprehend, therefore, that the Marine Biological Association, receiving as it does liberal support and recognition of the importance of its aims from the Government, should place at the disposal of the new Fishery Department any resources it may possess for the prosecution of such scientific investigations as the Department may wish to initiate.

The Council further desire me to say that they will be glad to enter into such relations with the Department as may seem to you best calculated to effect the object.

In making this offer the Council believe that they are carrying out the spirit of the conditions imposed upon them by my Lords in the letter of which a copy is inclosed.

I am, Sir, your most obedient servant,
E. RAY LANKESTER, Hon. Sec. M.B.A.
The Right Honourable A. J. Mundella, M.P.,
Board of Trade

To this letter the following answer was received :—

Board of Trade, Whitehall Gardens, S.W.,
April 8, 1886

SIR,—I am directed by Mr. Mundella to acknowledge the receipt of your letter of April 7, and to request that you will be so good as to convey to the Council of the Marine Biological Association his best thanks for their kind offer which they have made to place at the disposal of the new Fishery Department the resources which they possess for the prosecution of such scientific investigations as the Department may wish to initiate. Mr. Mundella wishes me to add that the matter is now receiving his most careful consideration.

I am, Sir, your obedient servant,
Prof. E. Ray Lankester T. W. P. BLOMEFIELD

IV. In reference to the building and aquarium fittings, which have been approved, and are now in course of construction for the Laboratory at Plymouth, the Council appointed, as stated in the last Annual Report, a Committee consisting of the Treasurer, the Secretary, Dr. John Evans, Prof. Moseley, and Mr. Spence Bate. These gentlemen, assisted by Mr. Walter Heape, Assistant Secretary, and by Mr. Inglis, civil engineer, of Plymouth, met on several occasions in order to consider the details of the Laboratory building and its fittings. Information and advice was obtained from the directors of the existing laboratories and aquariums in Europe and in the United States of America, as well as from engineering firms acquainted with the special kind of work required. The limitation of the funds at the disposal of the Council had to be strictly borne in mind by the Committee, and finally, after much deliberation, a plan of buildings and fittings was submitted by the Committee and approved by the Council. The approval of the War Office had to be obtained in regard to the design of the building which is to be erected on the site granted by that Department of State, and the Council has had the advantage in this connection of the advice and assistance of Mr. E. Bell, the architect to the War Office. The design, for which a contract has now been accepted by the Council, has the approval of the authorities of the War Office and of the Town Council of Plymouth.

V. Shortly after the annual meeting in June 1885, Mr. St. Leger Bunnett, of New Stone Buildings, 60, Chancery Lane, was appointed Assistant Secretary with the special purpose of aiding the Secretary in obtaining subscriptions and donations.

In January of the present year Mr. Walter Heape vacated his post of Assistant Secretary, and was appointed Resident Superintendent of the Plymouth Laboratory at a salary of 200*l*. a year. Mr. Heape will be provided with a suite of apartments in the Laboratory building. Since his appointment Mr. Heape has visited the Zoological Laboratory at Naples for the purpose of acquiring information which may assist him in the management of the Plymouth Laboratory. He will at once proceed to Plymouth and take up his residence there, in order to commence an investigation of the natural history of Plymouth Sound and to enter into relations with the fishermen of the district, so as to prepare the way for the operations of the Laboratory when completed. Mr. Heape will also watch the erection of the Laboratory building and report from time to time to the Council of the Association at Plymouth.

VI. The Council propose to make two alterations in the

by-laws of the Association which will require the approval of the present general meeting and of a subsequent special general meeting, which will be duly summoned. The first proposal is to enact by by-law of the Association that the Prime Warden of the Fishmongers' Company shall always be *ex officio* a member of the Council of the Association. The Fishmongers' Company have shown their interest in the enterprise of the Association by contributing 2000*l.* to its funds. In reply to an inquiry from the Council, the Court of Assistants of the Fishmongers' Company have cordially accepted the proposition that the Prime Warden of the Company should hold the official relation to the Association above proposed. The Council therefore propose to alter By-law 2 of the Association by the insertion between the words "officers" and "and fourteen other members" of the words "the Prime Warden of the Fishmongers' Company for the time being."

The second proposal has relation to the admission of the Universities of Great Britain and Ireland to a share in the government of the Association. As was stated in the last Annual Report, members of the University of Cambridge have subscribed a sum of 500*l.* for the purpose of qualifying the University as a Governor of the Association. During the past year a similar fund has been raised by members of the University of Oxford. At the annual general meeting in June 1885, in view of these proceedings, the following addition to By-law 17 was carried: "Any University of the United Kingdom, on the payment of 500*l.* to the Association by members of the University, shall, if the Council of the Association consent thereto, acquire as a consequence the perpetual right of nominating one member of the Council of the Association."

The Council now propose to erase the words just cited, and to substitute the following:—

"Any University of the United Kingdom, on the payment of 500*l.* to the Association in the name of the University and for the purpose of acquiring the right herein specified, shall, if the Council of the Association assent thereto, become a Governor of the Association, and acquire the perpetual right of nominating annually one member of the Council of the Association to serve for one year (from the annual meeting in one year to that in the following year); and any resident member of the University subscribing 100*l.* or more to such fund of 500*l.*, shall, in virtue of such subscription, become a 'Founder' of the Association."

VII. The Council have again to record a severe loss to the Association in the list of its Vice-Presidents owing to the death of Dr. W. B. Carpenter, C.B., F.R.S. Dr. Carpenter was a warm supporter of the Association, and contributed largely by his advocacy of its objects to the success which has now been attained.

VIII. The Council do not propose any change in the list of Officers, Vice-Presidents, and Council for the ensuing year. They desire to notify that the following gentlemen have qualified by subscription of 500*l.* each as Life-Members (Governors) of the Council, viz. Mr. Robert Bayly, of Plymouth, 1885; Mr. Bazley White (Clothworkers' Company), 1885; Mr. E. L. Beckwith (Fishmongers' Company), 1885; and Mr. John Bayly, of Plymouth, 1886.

IX. During the ensuing year the building at Plymouth will be in course of erection. It is anticipated that the chief duty of the Council during this period will be to organise a scheme of investigation to be carried out at Plymouth when the Laboratory is in working order.

It will be especially the business of the Council to determine the conditions under which the Laboratory shall be accessible to the naturalists of the United Kingdom and other countries for the purpose of aiding in those inquiries into the life-history of marine animals and plants, and particularly of food-fishes, which it is the purpose of the Association to foster.

X. The plan of the Laboratory building includes a library. The Council take the present opportunity of asking for donations of works relating to fisheries and to marine zoology and botany for the library. They will also be glad to receive subscriptions towards a special library fund, in reference to which and all similar matters, the Hon. Secretary, Prof. Lankester, can be consulted.

XI. In conclusion, the Council desire again to express the great obligation which the Association is under towards the Council of the Linnean Society for the continued permission accorded by that body to the Association to meet in the rooms of the Society.

MEMORANDUM RELATING TO THE MODE IN WHICH SCIENTIFIC KNOWLEDGE CAN BE MADE USEFUL TO ENGLISH FISHERIES

THE following Memorandum has been presented to the President of the Board of Trade and officially acknowledged by him:—

Without committing ourselves to all the statements and opinions contained in the subjoined Memorandum, we, the undersigned, wish to state that we concur generally with the views as to the proposed constitution of the new Fishery Department therein expressed—

Argyll, K.G., F.R.S.; Walsingham; Stalbridge; E. Marjoribanks, M.P., Member of the late Royal Commission on Trawling; John Lubbock, Bart., M.P., F.R.S.; James Paget, Bart., F.R.S.; Henry W. Acland, K.C.B., F.R.S.; J. Fayrer, K.C.S.I., F.R.S., Honorary Physician to the Queen, Physician to the Secretary of State for India in Council; C. Spence Bate, F.R.S., Member of Council of the Marine Biological Association; I. Bayley Balfour, F.R.S., Sherardian Professor of Botany in the University of Oxford; Ed. Lonsdale Beckwith, late Prime Warden of the Fishmongers' Company, Member of Council of the Marine Biological Association; F. Jeffrey Bell, F.Z.S., Professor of Zoology in King's College, London, Member of Council of the Marine Biological Association; Henry B. Brady, F.R.S.; W. S. Caine, M.P., Member of the late Royal Commission on Trawling; P. H. Carpenter, F.R.S.; W. H. Dallinger, F R.S., President of the Royal Microscopical Society; F. Darwin, F.R.S.; W. T. Thiselton Dyer, C.M.G., F.R.S., Director of the Royal Gardens, Kew, Member of Council of the Marine Biological Association; W. H. Flower, F.R.S., Superintendent of the British Museum, Natural History, President of the Zoological Society, Vice-President of the Marine Biological Association; Hans Gadow, Strickland Curator and Lecturer on Animal Morphology in the University of Cambridge; Arthur Gamgee, F.R.S., Fullerian Professor of Physiology in the Royal Institution of Great Britain; W. H. Gaskell, F.R.S.; A. Günther, F.R.S., Keeper of the Zoological Department of the British Museum, Member of Council of the Marine Biological Association; S. F. Harmer, Fellow of King's College, Cambridge; W. A. Herdman, Professor of Zoology in University College, Liverpool, Member of Council of the Marine Biological Association; G. M. Humphry, F.R.S., Professor of Surgery in the University of Cambridge, late Professor of Anatomy, Fellow of King's College; J. N. Langley, F.R S., Fellow of Trinity College, Cambridge; E. Ray Lankester, F.R S., Jodrell Professor of Zoology in University College, London, Fellow of Exeter College, Oxford, Hon. Sec. of the Marine Biological Association; A. Milnes Marshall, F.R.S., Professor of Zoology in Owens College, Manchester, Member of Council of the Marine Biological Association; W. C. McIntosh, F.R.S., Professor of Natural History in the University of St. Andrews, Vice-President of the Marine Biological Association; H. N. Moseley, F.R.S., Linacre Professor of Human and Comparative Anatomy in the University of Oxford, Chairman of Council of the Marine Biological Association; Geo. J. Romanes, F.R.S., Member of Council of the Marine Biological Association; J. Burdon Sanderson, F.R.S., Waynflete Professor of Physiology in the University of Oxford; E. A. Schäfer, F.R.S., Professor of Physiology in University College, London; P. L. Sclater, F.R.S., Secretary of the Zoological Society, Member of Council of the Marine Biological Association; Adam Sedgwick, F.R.S., Fellow of Trinity College, Cambridge, Member of Council of the Marine Biological Association; C. Stewart, F.L.S., Conservator of the Museum of the Royal College of Surgeons, Member of Council of the Marine Biological Association; D'Arcy W. Thompson, Professor of Zoology in University College, Dundee; Sydney H. Vines, F.R.S.; W. F. R. Weldon, Fellow of St. John's College, Cambridge; Frank Crisp, Vice-President of the Linnean Society, Hon. Treasurer of the Marine Biological Association; Peter Eade, President, on behalf of the Norfolk and Norwich Naturalists' Society; J. Gurney, Mayor of Norwich, R. E. Burroughes, H. W. Stafford, John B. Pearce, Harry Bullard, S. Gurney Buxton, and John Barwell, Conservators under the Norfolk and Suffolk Fisheries Act, 1877, for the City of Norwich; C. Louis Buxton, T. C. Blofeld, and E. Frost, Mayor of Thetford, Conservators for Norfolk; B. F. Grimsey, Mayor of Ipswich, and Lieut.-Col. H. M. Leathes, Conservators for Suffolk; F. B. Archer, Conservator for Lynn; C. J. Greene, Hon. Sec. of the

Yare Preservation Society; Lieut.-Col. F. H. Custance; Michael Beverley, M.D.; H. W. Bidwell; G. F. Buxton; H. W. Fielden, late Naturalist to Sir G. Nares's Arctic Expedition; Thos. Southwell.

I.—*Preface*

(1) The necessity for an administration of our marine and fresh-water fisheries based upon thorough or scientific knowledge of all that relates to them has become obvious of late years. The Trawling Commission of 1884–85 has reported to this effect in so far as the subject of their inquiries is concerned. Other nations have adopted such a method of dealing with their fisheries, with good results and the promise of better.

(2) The inquiries and operations necessary cannot be conducted as the result of private commercial enterprise. They must be national in character.

(3) Whilst the general trade returns of the fishing industry, on the one hand, and the practical enforcing of regulations as to the protection of fishing-grounds and the restriction of fishing operations within certain seasons and localities are matters with which an ordinary staff of officials can effectually deal, yet the chief purposes of the operation of a satisfactory Fisheries Department are of such a nature that only expert naturalists can usefully advise upon them and carry them out. It is therefore important that the organisation of a State Fisheries Department should either be primarily under the control of a scientific authority who should direct the practical agencies as to trade returns and police, or that there should be distinct and parallel branches of the Department—the one concerned in scientific questions, the other in collecting trade returns and in directing the fisheries police.

(4) It does not appear that there is any ground for supposing that individuals of scientific training are *ipso facto* unfitted for administrative duties, and there would be obvious advantages in placing the operations of a Fisheries Department under one head. Indeed, it may be maintained that an education in scientific matters, and capacity for scientific work, is likely to produce a more practical and enterprising director of such a Department than could elsewhere be found. It has not been found desirable to place the administration of the important botanical institution at Kew in the hands of a non-scientific director, and there is no obvious reason for avoiding the employment of a scientific staff in the case of a Fisheries Department.

II.—*Nature of the Work to be done*

(1) Generally to ascertain what restrictions or modifications in the proceedings of fishermen are desirable, so as to insure the largest and most satisfactory returns prospectively as well as immediately from the fishing-grounds of the English coast and from English rivers and lakes.

(2) Especially to ascertain whether existing fishing-grounds can be improved by the artificial breeding of food-fishes and shell-fish, and to determine the methods of carrying on such breeding, and to put these methods into practice.

(3) To find new fishing-grounds.

(4) To introduce new fish—either actually new to the locality or new to the consumer.

(5) To introduce (if practicable) methods of rearing and fattening marine fish in stock-ponds.

(6) To look after the cultivation and supply of bait.

(7) To introduce new baits, new methods of fishing, improved nets, improved boats, new methods of transport and of curing.

The work can be divided into two sections. A. Investigation; B. Practical Administration.

A. *Investigation.*—The inquiries which are necessary in order to effect the purposes indicated above are as follows:—

(1) A thorough physical and biological exploration of the British coasts within a certain distance of the shore-line, especially and primarily in the neighbourhood of fishing-grounds. The investigation must include a determination of temperature and currents at various depths, the nature of the bottom, the composition of the sea-water, and the influence of rivers and conformation of coast upon these features. At the same time the entire range of the fauna and flora must be investigated in relation to small areas so as to connect the varying living inhabitants of different areas with the varying physical conditions of those areas and with the varying association of the living inhabitants *inter se*. Only in this way can the relation of food-fishes to the physical conditions of the sea, and to their living associates be ascertained and data furnished for ultimately determining the causes of the local distribution of different kinds of food-fishes and of the periodic migrations of some kinds of them.

(2) A thoroughly detailed and accurate knowledge of the food, habits, and movements of each of the important kinds of food-fishes (of which about five-and-twenty, together with six shell-fish important either as food or bait, may be reckoned). The relation of each of these kinds of fish to its fishing-ground must be separately ascertained; its time and mode of reproduction, the mode of fertilisation of its eggs, the growth of the embryo, the food and habits of the fry, the enemies of the young and of the adult, the relation of both young and adult to temperature, to influx of fresh water, to sewage contamination, to disturbing agencies such as trawling, and ordinary traffic.

(3) An inquiry as to whether over a long period of years there has been an increase or a decrease in the abundance of each kind of food-fish on the chief fishing-grounds as a matter of fact, together with an inquiry as to the actual take of each kind of fish in successive years, and further an inquiry as to any accompanying variation in (*a*) the number of fishing-boats; (*b*) the methods of fishing; (*c*) the climatic conditions or other such possibly influential conditions as previous inquiry may have suggested.

(4) An inquiry for the purpose of ascertaining experimentally whether the decrease in the yield of fishing-grounds, in regard to each several species of food-fish can be remedied: (*a*) by artificial breeding of the fish; (*b*) by protecting the young; (*c*) by increasing its natural food; (*d*) by destruction of its enemies; (*e*) by restrictive legislation as to time or place of fishing and as to size of fish which may be taken and character of fishing apparatus which may be used.

(5) An inquiry to ascertain whether, if periodic, natural causes are at work in determining the fluctuations of the yield of fishing-grounds, their effect can be foretold, and whether this effect can in any case be counteracted; similarly to ascertain in the case of migratory shoal-fish whether any simple and trustworthy means can be brought into operation for the purpose of foretelling the places and times of their migrations so as to enable both fishermen and fish-dealers to be ready for their arrival.

(6) An inquiry into the diseases of fish, especially in relation to salmon and other fresh-water fish.

B. *Practical Administration.*—The chief heads under which this presents itself as distinct from the antecedent search for reliable data are:—

(1) The management of an efficient "intelligence department," giving weekly statistics of the fishing industry, the appearance and disappearance of certain fish at particular spots, the number of fishing-boats employed, the methods of fishing employed, the meteorological conditions.

(2) The advising and enforcing of restrictions by the Legislature as to time, place, and method of capture of fish.

(3) The artificial breeding and rearing of fish to stock impoverished fishing-grounds.

(4) The leasing and management of the foreshore and sea-bottom in particular spots, for the purposes of oyster-culture and mussel-culture, and of marsh-lands near the sea for the formation of tanks and fish-ponds.

(5) The opening up of new fishing-grounds and of new fish industries (curing and treatment of fish for commercial purposes).

(6) The introduction of new species of food-fish and shell-fish.

III.—*General Organisation and Staff necessary to carry on the Inquiries and to put the Results attained into Practice*

It is a matter of fundamental importance to determine, first of all, whether it is desirable that these matters should be dealt with by a permanent staff, or, on the other hand, by the occasional employment of a scientific man—not habitually occupied in these inquiries—to attempt the solution of any particular problem which an unskilled official may present to him.

Clearly there must be economy in employing permanently certain naturalists who will familiarise themselves with this

special class of questions and become experts in all that relates to fishery problems.

Further, is it desirable that the matters which are to be inquired into should be determined by an official unskilled in natural history? Or, on the other hand, that the selection of inquiries likely to lead to a satisfactory result should be made by a man of science, specially conversant with the nature of the things to be dealt with?

The organisation required consists, so far as persons are concerned, of:—

(1) A chief scientific authority.

(2) A staff of working naturalist-inspectors.

(3) A staff of clerks.

And, so far as material is concerned, of:—

(4) A London office, with collection of fishes, apparatus used in fishing, maps, survey-records, statistical returns, and library.

(5) A surveying-ship, under the orders of the Department, to be manned and maintained by the Admiralty.

(6) A chief laboratory fitted for carrying on investigations such as those named in Section II., and also two smaller movable laboratories, together with steam yacht fitted for dredging and sounding.

(7) Hatching-stations and fish-ponds.

With regard to the foregoing headings, it is a matter for consideration whether "the chief scientific authority" should be an individual or a committee of five. The position assigned to this post should be equal to that of the Director of the Geological Survey or the Director of the Royal Gardens, Kew, or, if the "authority" takes the form of a committee, it should be placed on the same footing as the Meteorological Council. The person or persons so appointed should be responsible for all the operations of the Department, and of such scientific training and capacity as to be likely to devise the most useful lines of inquiry and administration.

The "naturalist-inspectors" should be six in number, but operations might be commenced with a smaller staff. They should be thoroughly competent observers, and under the direction of the chief scientific authority they would be variously employed, either on the surveying-ship, at the chief laboratory, or in local laboratories, hatching-stations, or in the London office and museum.

The naturalists thus employed would become specialists in all matters relating to the life-history of fishes and their food; they would acquire a skill and knowledge far beyond that which it is possible to find amongst existing naturalists, who occasionally are requested to make hurried reports on such matters as salmon disease or the supposed injury of the herring-fisheries by trawlers.

One of the naturalist-inspectors should be a chemist and physicist, in order to report on the composition of the water and the nature of the bottom in the areas investigated.

"Clerks" would be required in the London office to tabulate statistics and carry on correspondence. These gentlemen need not necessarily have any scientific knowledge. It would probably be necessary to have a correspondent or agent of the Department in every large fishing centre. Probably the coast-guard officials might be taken into this service.

With regard to material equipment it appears to be necessary that a Scientific Fisheries Department should have at its London office a Museum of fishing apparatus for reference and instruction, and also complete collections illustrative of the fishes, their food, enemies, and other surroundings. In the same building would be exhibited maps showing the distribution and migrations of food-fishes, the coast temperature and its variations, the varying character of the sea-bottom, sea-water, &c.

The surveying-ship or ships would be provided by the Admiralty.

A central laboratory is in course of erection upon Plymouth Sound by the Marine Biological Association. Her Majesty's Government has promised to contribute 5000*l.* and 500*l.* a year to this institution, on condition that its resources are available for the purpose here indicated. Certain of the "naturalist-inspectors" (probably three at any one time) would be stationed at the Plymouth laboratory in order to carry on special studies of the development and food of particular species of fish.

The smaller movable laboratories, steam-yacht, and other appliances would not be costly.

ON NEW APPLICATIONS OF THE MECHANICAL PROPERTIES OF CORK TO THE ARTS[1]

IT would seem difficult to discover any new properties in a substance so familiar as cork, and yet it possesses qualities which distinguish it from all other solid or liquid bodies, namely, its power of altering its volume in a very marked degree in consequence of change of pressure. All liquids and solids are capable of cubical compression, or extension, but to a very small extent; thus water is reduced in volume by only 1/2000 part by the pressure of one atmosphere. Liquid carbonic acid yields to pressure much more than any other fluid, but still the rate is very small. Solid substances, with the exception of cork, offer equally obstinate resistance to change of bulk; even india-rubber, which most people would suppose capable of very considerable change of volume, we shall find is really very rigid.

I have here an apparatus for applying pressure by means of a lever. I place a piece of solid india-rubber under the plate and you see that I can compress it considerably by a very light pressure of my finger. I slip this same piece of india-rubber into a brass tube, which it fits closely, and now you see that I am unable to compress it by any force which I can bring to bear. I even hammer the lever with a mallet, and the blow falls as it would on a stone. The reason of this phenomenon is, that in the first place, with the india-rubber free, it spread out laterally while being compressed longitudinally, and consequently the volume was hardly altered at all; in the second case, the strong brass tube prevented all lateral extension, and because india-rubber is incapable of appreciable cubical compression, its length only could not be sensibly altered by pressure.

Extension, in like manner, does not alter the volume of india-rubber. In this glass tube is a piece of solid round rubber which nearly fills the bore. The lower end of the rubber is fixed in the bottom of the tube, and the upper end is connected by a fine cord to a small windlass, by turning which I can stretch the rubber. I fill the tube to the brim with water, and throw an image of it on to the screen. If stretching the rubber either increases or diminishes its volume, the water in the tube will either overflow or shrink in it. I now stretch the rubber to about 3 inches, or one-third of its original length, but you cannot see any appreciable movement in the water-level, hence the volume of the rubber has not changed.

Metals when subjected to pressures which exceed their elastic limits, so that they are permanently deformed, as in forging or wire-drawing, remain practically unchanged in volume per unit of weight.

I have here a pair of common scales. To the under sides of the pans I can hang the various specimens that I wish to examine; underneath these are small beakers of water which I can raise or lower by means of a rack and pinion. Substances immersed in water lose in weight by the weight of their own volume of water; hence if two substances of equal volume balance each other in air, they will also balance when immersed in water, but if their volumes are not the same, then the substance having the smaller volume will sink, because the weight of water it displaces is less than that displaced by the substance with the larger volume. To the scale on your left hand is suspended a short cylinder of ordinary iron, and to the right-hand scale a cylinder of ordinary copper. They balance exactly. I now raise the beakers and immerse the two cylinders in water; you see the copper cylinder sinks at once, and I know by that that copper has a smaller volume per pound than iron, or, as we should commonly say, it is heavier than iron. I now detach the copper cylinder, and in its place hang on this iron one, which is made of the same bar as its fellow cylinder, but forced, while red hot, into a mould by a pressure of sixty tons per square inch and allowed to cool under that pressure. The two cylinders balance, as you see. Has the volume of the iron in the compressed cylinder been altered by the rough treatment it has received? I raise the beakers, immerse the cylinders, the balance is not destroyed; hence we conclude that although the form has been changed the volume has remained the same. I substitute for the hot compressed cylinder one pressed into a mould while cold, and held there for some time, with a load of sixty tons per square inch; the balance is not destroyed by immersion, hence the volume has not been altered. I can repeat the experiments with these copper cylinders and the

[1] A Paper read at the Royal Institution of Great Britain on April 9, 1886, by William Anderson, M.Inst.C.E., M.R.I.

result will be found the same. Extension also is incapable of appreciably altering the density of metals. I attach to the scales two specimens of iron taken from a bar which had been torn asunder by a steady pull. One specimen is cut from the portion where it had not been strained, and the other from the very point where it had been gradually drawn out and fractured. The specimens balance, I immerse them, you see the balance is not destroyed; hence the volume of the iron has not been changed appreciably by extension.

But cork behaves in a very different manner. I place this cylinder of cork into just such a brass tube as served to restrain the india-rubber and apply pressure to it in the same way; you see I can readily compress the cork, and when I release it it expands back to its original volume: the action is a little sluggish on account of the friction of the cork against the sides of the tube. In this case, therefore, a very great change in the volume of the material has been easily effected.

But although solids evidently do not change sensibly in bulk, after having been released from pressures high enough to distort them permanently, yet, while actually under pressure, the volumes may have been considerably altered. As far as I am aware, this point has not been determined experimentally for metals, but it is very easy to show that india-rubber does not change.

I have here some of this substance, which is so very slightly lighter than water, that, as you see, it only just floats in cold water but sinks in hot. If I could put it under considerable pressure while afloat in cold water, then, if its volume became sensibly less, it ought to sink. In the same way, if I load a piece of cork and a piece of wood so that they barely float, if their volumes alter they ought to sink.

In this strong upright glass tube I have, at the top, a piece of india-rubber, immediately below it a piece of wood, and below that a cork; the wood and the cork are loaded with metal sinkers to reduce their buoyancy. The tube is full of water and is connected to a force-pump by means of which I can impose a pressure of over 1000 lbs. per square inch. The image of the tube is now thrown on the screen and the pressure is being applied. You see at once the cork is beginning to shrink in all directions, and now its volume is so reduced that it is incapable of floating, and sinks down to the bottom of the tube. The india-rubber is absolutely unaffected, the wood does contract a little, but not sufficiently to be visible to you or to cause it to sink. I open a stop-cock and relieve the pressure; you see that the cork instantly expands, its buoyancy is restored, and it floats again. By alternately applying and taking off the pressure I can produce the familiar effect so well known in the toy called "the bottle imps." It is this singular property which gives to cork its value as a means of closing the mouths of bottles. Its elasticity has not only a very considerable range, but it is very persistent. Thus in the better kind of corks used in bottling champagne and other effervescing wines you are all familiar with the extent to which the corks expand the instant they escape from the bottles. I have measured this expansion, and find it to amount to an increase of volume of 75 per cent., even even after the corks have been kept in a state of compression in the bottles for ten years. If the cork be steeped in hot water, the volume continues to increase till it attains nearly three times that which it occupied in the neck of the bottle.

When cork is subjected to pressure, either in one direction, as in this lever press, or from every direction, as when immersed in water under pressure, a certain amount of permanent deformation or "permanent set" takes place very quickly. This property is common to all solid elastic substances when strained beyond their elastic limits, but with cork the limits are comparatively low. You have, no doubt, noticed in chemists' and other shops that, when a cork is too large to fit a bottle, the shopkeeper gives the cork a few sharp bites, or, if he be more refined, he uses a pair of specially-contrived pincers; in either case he squeezes the cork beyond its elastic limits, and so makes it permanently smaller. Besides the permanent set, there is a certain amount of what I venture to call sluggish elasticity, that is, cork on being released from pressure, springs back a certain amount at once, but the complete recovery takes an appreciable time.

While I have been speaking, a piece of fresh cork, loaded so as barely to float, has been inserted into the vertical glass pressure-tube. I apply a slight pressure, you see the cork sinks. I release the pressure, and it rises briskly enough. I now apply a much higher pressure for a moment or two, I release it, and the cork will either not rise at all, or will do so very slowly; its volume has been permanently altered; it has taken a permanent set.

In considering the properties of most substances, our search for the cause of these properties is baffled by our imperfect powers and the feeble instruments we possess for investigating molecular structure. With cork, happily, this is not the case; an examination of its structure is easy, and perfectly explains the cause of its peculiar and valuable properties.

All plants are built up of minute cells of various forms and dimensions. Their walls or sides are composed chiefly of a substance called cellulose, frequently associated with lignine, or woody matter, and with cork, which last is a nitrogenous substance found in many portions of plants, but is especially developed in the outer bark of exogenous trees, that is, trees belonging to an order, by far the most common in these latitudes, the stems of which grow by the addition of layers of fresh cellulose tissue outside the woody part and inside the bark. Between the bark and the wood is interposed a thin fibrous layer, which, in some trees, such as the lime, is very much developed, and supplies the bass matting with which all are familiar. The corky part of the bark, which is outside, is composed of closed cells exclusively, so built together that no connection of a tubular nature runs up and down the tree, although horizontal passages radiating towards the woody part of the tree are numerous. In the woody part of the tree, on the contrary, and in the inner bark, vertical passages or tubes exist, while a connection is kept up with the pith of the tree by means of medullary rays. In one species of tree, known as the cork oak, the corky part of the bark is very strongly developed. I project on the screen the magnified image of a horizontal section of the bark of the cork oak; you see nine or ten bands running parallel to each other: these are the layers of cellulose matter that have been deposited in successive years. I turn the specimen, and you now see the vertical section with the radiating passages clearly marked.

The difference between the arrangement of the cells or tissue forming the woody part of the tree and the bark is easily shown. I have here three metal sockets, supported over a shallow wooden tray. Into them are fitted, first, a cork cut out of the bark in a vertical direction, next, a cork cut in a radial direction, and, lastly, a piece of common yellow pine. By means of my force-pump, I apply a couple of atmospheres of hydraulic pressure. I project an image of the apparatus on the screen, and you see the water has made its way through the wood and through the cork cut in the radial direction, while the cork cut in the vertical direction is impervious.

The cork tree, a species of evergreen oak, is indigenous in Portugal and along both shores of the Mediterranean. The diagram on the wall has been painted from a sketch obligingly sent to me by Mr. C. A. Friend, the resident engineer of the Seville Waterworks, to whom I am also indebted for this branch of a cork tree, these acorns, this axe used in getting the cork, and for a description of the habits of the tree, its cultivation, and the mode of gathering the harvest.

The cork oak attains a height of 30 to 40 feet; it is not cultivated in any way, but grows like trees in a park. The first crop is not gathered till the tree is thirty years old, the next nine or ten years later; both these crops yield inferior cork, but at the third crop, gathered when the tree is fifty years old, the bark has attained full maturity, and after that will yield the highest quality of cork every nine or ten years. In the autumn of the year, when the bark is in a fit state, that is, for small trees, from three quarters of an inch to one inch thick, and for larger ones up to one inch and a half, a horizontal cut is made, by means of a light axe like the one I hold in my hand, through the bark a few inches above the ground; succeeding cuts are made at distances of about a yard, up to the branches, and even along some of the large ones, then two or more vertical cuts, according to the size of the tree, and the bark is ripped off by inserting the wedge-shaped end of the axe-handle. In making the cuts great care is taken to avoid wounding the inner bark, upon the integrity of which the health of the tree depends; but where this precaution is taken, the gathering of the cork does not in any way injure the tree.

After stripping, the cork is immersed for about an hour in hot water, it is dressed with a kind of spokeshave, then laid out flat and weighted in order to take out the curvature; it is then stacked in the open air, without protection of any kind, for cork does not appear to be susceptible of receiving injury from the weather.

The minute structure of the bark is very remarkable. First, I project on the screen a microscopic section of the wood of the cork tree. It is taken in a horizontal plane, and I ask you to notice the diversity of the structure, and especially the presence of large tubes or pipes. I next exhibit a section taken in the same plane of the corky portion of the bark. You see the whole substance is made up of minute many-sided cells about 1/750 of an inch in diameter, and about twice as long, the long way of the cells being disposed radially to the trunk. The walls of the cells are extremely thin, and yet they are wonderfully impervious to liquids. Looked at by reflected light, if the specimen be turned, bands of silvery light alternate with bands of comparative darkness, showing that the cells are built on end to end in regular order. The vertical section next exhibited shows a cross section of the cells looking like a minute honeycomb. In some specimens large numbers of crystals are found. These could not be distinguished from the detached elementary spindle-shaped cells, of which woody fibre is made up, were it not for the powerful means of analysis we have in polarised light. I need hardly explain to an audience in this Institution that light passed through a Nicol prism becomes polarised, that is to say, the vibrations of the luminiferous ether are all reduced to vibrations in one plane, and, consequently, if a second prism be interposed and placed at right angles to the first, the light will be unable to get through; but if we introduce between the crossed Nicols a substance capable of turning the plane of vibration again, then a certain portion of the light will pass. I have now projected on the screen the feeble light emerging from the crossed Nicols. I introduce the microscopic preparation of cork cells between them, and you see the crystals glowing with many-coloured lights on a dark ground.

Minute though these crystals are, they are very numerous and hard, and it is partly to them that is due the extraordinary rapidity with which cork blunts the cutting instruments used in shaping it. Cork-cutters always have beside them a sharpening-stone, on which they are obliged to restore the edges of their knives after a very few cuts.

The cells of the cork are filled with gaseous matter, which is very easily extracted, and which has been analysed for me by Mr. G. H. Ogston, and proved to be common air. I have here a glass tube in which are some pieces of cork which have been cut into slices so as to facilitate the escape of the air. I connect the tube with an exhausted receiver and project the image on the screen; you see rising from the cork bubbles of air as numerous, but much more minute than the bubbles which rise from sparkling wines; much more minute, because the bubbles you see are expanded to seven or eight times their volume at atmospheric pressure on account of the vacuum existing in the tube. The air will continue to come off for an hour or more, and from measurements made by Mr. Ogston I find that the air occluded in the cork amounts to about 53 per cent. of its volume. The facility with which the air escapes, compared with the impermeability of cork to liquids is very remarkable.

I throw on the screen the image of a section cut from a cork which was kept under a vacuum of about 26 inches for five days and nights; aniline dye was then injected, and yet you see that the colour has not more than permeated the outermost fringe of cells—those, in fact, which had been broken open by the operation of cutting the cork. By keeping cork for a very long time in an almost perfect vacuum, and then injecting dye, a slight darkening of the general colour of a section of the cork may be noticed, but it is very slight indeed. How, then, does the air escape so readily when the cork is placed *in vacuo?*

The answer is, that gases possess the property of diffusion; that is, of passing through porous media of inconceivable fineness. When two gases, such as hydrogen and air, are separated by a porous medium, they immediately begin to pass into each other, and the lighter gas passes through more quickly than the heavier.

I have here a glass tube, the upper end of which is closed by a thin slice of cork, the lower end dips into a basin of water. Some hours ago the tube was filled with hydrogen, which you know is about $14\frac{1}{2}$ times lighter than air; consequently, according to the law of diffusion, it will get out of the tube through the cork quicker than the air can get in by the same means, and the result must be that a partial vacuum will be formed in the tube, and a column of water will be drawn up. You see that such has been the case, and we have thus proved that the cells of cork are eminently pervious to gases. The pores in the cell-walls appear, however, to be too minute to permit the passage of liquids.

I closed the end of a glass tube 11 mm. diameter, with a disk of cork 1·75 mm. thick, cut at right angles to the axis of the tree; I placed a solution of blue litmus inside the tube, and suspended it in a weak solution of sulphuric acid. Had diffusion taken place, both liquids would have assumed a red colour, but after sixteen hours no change whatever could be detected. A like inertness was exhibited when the tube was filled with a solution of copper sulphate and suspended in a weak solution of ammonia; a deep blue colour would have appeared had any intermixture taken place, and the same tube is before you immersed in ammonia and filled with red litmus solution. It has been in this condition since February 28, but no diffusion has taken place. A disk of wood 6 mm. thick under the same circumstances showed, after a couple of hours, by the liquids turning blue, that diffusion was going on actively. It is this property of allowing gases to permeate while completely barring liquids that enables cork to be kept in compression under water or in contact with various liquids without the air-cells becoming water-logged, and that makes cork so admirable an article for waterproof wear, such as boot-soles and hats, for, unlike india-rubber, it allows ventilation to go on while it keeps out the wet. The cell-walls are so strong, notwithstanding their extreme thinness, that they appear, when empty, to be able to resist the atmospheric pressure, for the volume of the cork does not sensibly diminish, even when all the air has been extracted. Viewed under very high power, cross-stays or struts of fibrous matter may be distinguished traversing the cells: these, no doubt, add to the strength and resistance of the structure.

From what you have seen you will have no difficulty in arriving at the conclusion that cork consists, practically, of an aggregation of minute air-vessels, having very thin, very water-tight, and very strong walls, and hence, if compressed, we may expect the resistance to compression to rise in a manner more like the resistance of gases than the resistance of an elastic solid such as a spring. In a spring the pressure increases in proportion to the distance to which the spring is compressed, but with gases the pressure increases in a much more rapid manner; that is, inversely as the volume which the gas is made to occupy. But from the permeability of cork to air, it is evident that, if subjected to pressure in one direction only, it will gradually part with its occluded air by effusion, that is by its passage through the porous walls of the cells in which it is contained. This fact can be readily demonstrated by the lever press which I have used, for, if the brass cylinder containing the cork be filled with soap and water and pressure be then applied, minute bubbles will be found to collect on the surface, and their formation will go on for many hours.

On the other hand, if cork be subjected to pressure from all sides, such as operates when it is immersed in water under pressure, then the cells are supported in all directions, the air in them is reduced in volume, and there is no tendency to escape in one direction more than another. An india-rubber bag, such as this, distended by air, bursts, as you see, if pressed between two surfaces, but if an india-rubber cell be placed in a glass tube and subjected to hydraulic pressure, it is merely shrivelled up; the strain on its walls is actually reduced.

To take advantage of the peculiar properties of cork in mechanical applications, it is necessary to determine accurately the law of its resistance to compression, and for this purpose I instituted a series of experiments of this kind. Into a strong iron vessel of $5\frac{1}{2}$ gallons capacity I introduced a quantity of cork, and filled the interstices full of water, carefully getting out all the air. I then proceeded to pump in water, until definite pressures up to 1000 pounds per square inch had been reached, and, at every 100 pounds, the weight of water pumped in was determined. In this way, after many repetitions, I obtained the decrease of volume due to any given increase of pressure. The observations have been plotted into the form of a curve, which you see on the diagram on the wall. The base-line represents a cylinder containing one cubic foot of cork divided by the vertical lines into ten parts; the black horizontal lines according to the scale on the left hand represent the pressures in pounds per square inch which were necessary to compress the cork to the corresponding volume. Thus to reduce the volume to one-half, required a pressure of 250 pounds per square inch. At 1000 pounds per square inch the volume was reduced to 44 per cent.; the yielding then became very little, showing that the solid parts of the cells had nearly come together, and this corroborates Mr. Ogston's determination that the gaseous part of cork constitutes 53 per cent. of its bulk. The engineer, in dealing with a compressible substance, requires to know not only the pressure which a given

change of volume produces, but also the work which has to be expended in producing the change of volume. The work is calculated by multiplying the decrease of volume by the mean pressure per unit of area which produced it. The ordinates of the dotted curve on the diagram with the corresponding scale of foot-pounds on the right-hand side are drawn equal to the work done in compressing a cubic foot of cork to the several volumes marked on the base-line. I have not been able to find an equation to the pressure curve; it seems to be quite irregular, and hence the only way of calculating the effects of any given change of volume is to measure the ordinates of the curve constructed by actual experiment. As may be supposed the pressures indicated by experiment are not nearly so regular and steady as corresponding experiments on a gas would be, and the actual form of the curves will depend on the quality of the cork experimented on.

The last point of importance in this inquiry relates to the permanence of elasticity in cork.

So far as preservation of elasticity during years of compression is concerned, we have the evidence of wine corks to show that a considerable range of elasticity is retained for a very long time. With respect to cork subjected to repeated compression and extension, I have very little evidence to offer beyond this, that cork which had been compressed and released in water many thousand times had not changed its molecular structure in the least, and had continued perfectly serviceable. Cork which has been kept under a pressure of three atmospheres for many weeks appears to have shrunk to from 80 to 85 per cent. of its original volume.

I will conclude this lecture by bringing under your notice two novel applications of cork to the arts.

Before the lecture-table stands a water-raising apparatus called a hydraulic ram. The structure of the machine is shown by a diagram on the wall. The ram consists of an inclined pipe, which leads the water from a reservoir into a chamber which terminates in a valve opening inwards. Branching up from the chamber is a passage leading to a valve, opening outwards and communicating with a regulating vessel, which is usually filled with air, but which I prefer to fill with cork and water. Immediately beyond the inner valve is inserted a delivery pipe, which is laid to the spot to which the water has to be pumped, in this case to the fountain jet in the middle of this pan.

The action of the ram is as follows:—The outer valve, which opens inwards, is, in the first instance, held open, and a flow of water is allowed to take place through it down the pipe and chamber. The valve is then released, and is instantly shut by the current of water which is thus suddenly stopped, and, in consequence, delivers a blow similar to that produced by the fall of a hammer on an anvil, and just as the hammer jumps back from the anvil, so does the water recoil back to a small extent along the pipe.

During this action, first, a certain portion of water is forced by virtue of the blow through the inner valve, opening outwards, into the cork vessel, and so to the delivery pipe, and instantly afterwards the recoil causes a partial vacuum to form in the body of the ram, and permits the atmospheric pressure to open the outer valve and re-establish a rush of water as soon as the recoil has expended itself. In the little ram before you, this action, which it has taken so long to describe, is repeated 140 times in a minute.

The ram is now working. You hear the regular pulses of the valve, and you see a jet of water rising some 10 feet into the air. I throw the electric light on the water, and I ask you to notice the regularity of the flow. You can, indeed, detect the pulses of the ram in the fountain, but that is because I am only using a regulating vessel of the same capacity as that generally used for air, and you will recollect that 44 per cent. of the substance of cork is solid and inelastic. By closing a cock I can cut off the cork vessel from the ram; you see the regularity of the jet has disappeared, it now goes in leaps and bounds. This demonstrates that the elasticity of cork is competent to regulate the flow of water. When air is used for this purpose the air-vessel has to be filled, and, with most kinds of water, the supply has to be kept up while the ram is working, because water under pressure absorbs air. For this purpose a "sniff-valve" is a necessary part of all rams. It is a minute valve opening inwards, placed just below the inner valve; at each recoil a small bubble of air is drawn in and passed into the air-vessel. This "sniff-valve" is a fruitful source of trouble. Its minuteness renders it liable to get stopped up by dirt; it must not, of course, be submerged, and, if too large, it seriously affects the duty performed by the ram. The use of cork gets rid of all these difficulties, no sniff-valve is needed, the ram will work deeply submerged, and there is no fear of the cork vessel ever getting empty. The duty which even the little ram before you has done is 65 per cent., and larger ones have reached 80 per cent.

The second novel application of cork is for the purpose of storing a portion of the energy of the recoil of cannon, for the purpose of expending it afterwards in running them out.

The result of the explosion of gunpowder in a gun is to drive the shot out in one direction, and to cause the gun to recoil with equal energy the opposite way. To restrain the motion of the gun "compressors" of various kinds are used, and in this country, for modern guns, they are generally hydraulic, that is to say, the force of recoil is expended in causing the gun to mount an inclined plane, and, at the same time, in driving a piston into a cylinder full of water, the latter being allowed to squeeze past the piston through apertures, the areas of which are either fixed or capable of being automatically varied as the gun recedes; or else the water is driven out of the cylinder through loaded valves. As a rule, the gun is moved out again into its firing position by its weight causing it to run down the inclined plane, up which it had previously recoiled. For naval purposes, however, this plan is inconvenient, because the gun will not run out to windward if the vessel is heeling over, on account of the inclined plane becoming more horizontal, or even inclined in the reverse direction, and should the ship take a permanent list, from a compartment getting full of water, the inconvenience might be very considerable.

In land service guns, when mounted in barbette, the rising of the gun exposes it and the loading detachment more to the enemy's fire, and in both cases, when placed in ports or embrasures, the ports must be higher than if the gun recoiled horizontally, and will therefore offer a better mark to the enemy's fire, especially that of machine guns, while the sudden rise of the gun in recoiling imposes a severe downward pressure on the deck or on the platform.

To obviate these disadvantages I have contrived the gun-carriage a model of which is before you on the table, and a diagram of which on the wall illustrates the internal construction. The gun is mounted on a carriage composed of two hydraulic cylinders, united so as to form one piece. The carriage slides on a pair of hollow ways, and also on to a pair of fixed rams, the rear ends of which are attached to the piece forming the rear of the mounting. There are water passages down the axes of the rams, and these communicate through an automatic recoil-valve, opening from the cylinders, with the two hollow slides. There is a second communication between the cylinders and slides by means of a cock, which can be opened or shut at pleasure. The hollow slides are packed full of cork and water, the latter also completely filling the cylinders, rams, and various connecting passages.

By means of a small force-pump enough water can be injected to give the cork so much initial compression as will suffice to run the gun out when the slides are inclined under any angle which may be found convenient.

When the gun is fired, the cylinders are driven on to the rams, and the water in the cylinders is forced through the hollow rams into the cork and water vessels formed by the slides, and the cork is compressed still farther. When the recoil is over, the automatic recoil-valve closes, and the gun remains in its rearward position ready for loading.

As soon as loaded, the running-out cock is opened, the expansion of the cork drives the water from around it into the cylinders, and so forces the gun out.

If it be desired to let the gun run out automatically immediately after recoil, it is only necessary to leave the running-out cock open, and then the water forced among the cork by recoil returns instantly to the cylinders, and runs the gun out quicker than the eye can follow the motion.

I will now load the model and fire a shot into this strong steel cylinder, at the bottom of which is a thick layer of soft wood. I will close the running-out valve, so that the gun shall remain in the recoiled position. Sir Frederick Abel has kindly arranged some of his electric fuses specially to fit this minute ordnance, and I can fire the gun by means of a small electro-magnetic battery. The gun has now recoiled, and remains in its rear position. I load again, open the running-out cock, the gun runs out, and I fire without closing the cock. You see the gun has recoiled and run out instantly again.

The arrangement I have adopted may be made by using air

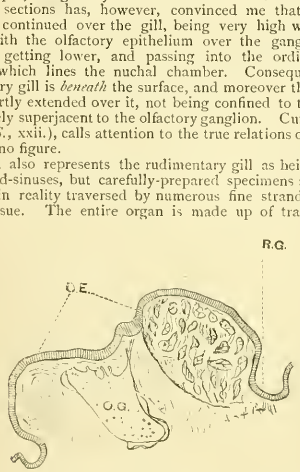
instead of cork, but air is a troublesome substance to deal with; it leaks out very easily, and without showing any signs of having done so, which might readily lead to serious consequences. A special pump is required to make up loss by leakage.

The merit of cork is its extreme simplicity and trustworthiness. By mixing a certain proportion of glycerine with the water it will not freeze in any ordinary cold weather.

NOTE ON THE RUDIMENTARY GILLS, ETC., OF THE COMMON LIMPET (PATELLA VULGATA)

SPENGEL, in his admirable paper "Die Geruchsorgane und das Nervensystem der Mollusken" (*Zeitschrift f. wiss. Zool.* xxxv.), figures a transverse section of one of the rudimentary gills and its surroundings. This appears to be incorrect in one or two particulars. In the first place the gill is figured as projecting freely at the surface. The examination of numerous sections has, however, convinced me that the epithelium is continued over the gill, being very high where continuous with the olfactory epithelium over the ganglion, but gradually getting lower, and passing into the ordinary epithelium, which lines the nuchal chamber. Consequently the rudimentary gill is *beneath* the surface, and moreover the sensory tract is partly extended over it, not being confined to the region immediately superjacent to the olfactory ganglion. Cunningham (*Q.J.M.S.*, xxii.), calls attention to the true relations of the gill, but gives no figure.

Spengel also represents the rudimentary gill as being full of large blood-sinuses, but carefully-prepared specimens show that these are in reality traversed by numerous fine strands of connective-tissue. The entire organ is made up of trabeculæ of



Transverse Section of Rudimentary Gill, &c., of *Patella vulgata* (× 90). R.G. Rudimentary gill; O.E. olfactory epithelium; O.G. olfactory ganglion.

connective-tissue, amongst which connective-tissue corpuscles abound. In some of the lacunæ masses of blood-corpuscles may be found.

Several small nerves run from the olfactory ganglion to the olfactory epithelium, and in some specimens nerve-fibres can almost be traced into the sense-cells. Gibson ("Anatomy of *Patella vulgata*," *Trans. R.S.E.*, xxxii.) has been unable to detect an olfactory ganglion. This is, however, very evident in microscopic sections.

I have used the term "rudimentary gills," for there seems little doubt that the structures in question are, as Spengel advocates, of this nature, but, lying as they do beneath the surface, they can hardly be functional. This position, too, suggests that these organs must have been rudimentary for a very long time. As Patella (Palacmæa) occurs in the fossil state as far back as the Middle Cambrian (Sedg.), the pallial gills may have been developed for a considerable period.

If, as Spengel believes, the molluscan olfactory organ enables the animals of that group to perceive the quality of the water passing over the gills, it is difficult to understand its well-developed state in Patella, where its position would appear to prevent such a use. Hence the olfactory organ in this form probably has some other function—possibly it may have something to do with the locality-sense, though this is very improbable (see note by author on "The Habits of the Limpet," NATURE, vol. xxxi. p. 200). The preceding observations were made at the Scottish Marine Station.

J. R. AINSWORTH DAVIS

University College, Aberystwyth

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—At the annual Scholarship election at St. John's College the following awards were made to students of Mathematics and Natural Science:—Hutchinson Studentship of 60*l.* a year for two years to A. C. Seward (First Class Nat. Sciences Tripos, Part II.), to enable him to follow up his researches in Fossil Botany; Hockin Prize for Physics with especial reference to Electricity, to Stroud (First Class Nat. Sciences Tripos, Part II.); Herschel Prize for Astronomy to Fletcher (Second Wrangler); Hughes Prizes for Mathematics to Fletcher, and for Natural Science to Rolleston (First Class Nat. Sciences Tripos, Part II.); Wright's Prizes for Mathematics to Baker and Orr, for Natural Science to Lake and Groom; Foundation Scholarships in Mathematics to Middlemast, Pressland, Tate, Bradford, Flux, and in Natural Science to Lake and W. Harris; extension of tenure of Scholarships to Kirby, Mossop, Bushe-Fox, and Baker in Mathematics, and to Shore and Turpin in Natural Science; Exhibitions in Mathematics to Hill, Fletcher, A. E. Foster, Norris, Varley, H. H. Harris, Orr, Greenidge, Flux, Card, Palmer, Millard, and in Natural Science to Lake, Groom, Rolleston, Seward, W. Harris; a Proper Sizarship in Natural Science to Cowell.

The following gentlemen have obtained first-class honours in the Natural Sciences Tripos, Part II., the subject for which they were specially classed being given after the name:—Carnegie, Chemistry, Caius; Edkins, Physiology, Caius; Hawkridge, Geology, Clare; Hudson, Physics, Pembroke; F. W. Oliver, Botany, Trinity; Rolleston, Human Anatomy with Physiology, St. John's; Seward, Geology, St. John's; Skinner, Chemistry, Christ's; Stroud, Physics, St. John's. Miss Freund, of Girton, was placed in the first class for Chemistry.

Messrs. Dixon, of Trinity College, and Fletcher, of St. John's, are respectively Senior and Second Wranglers. Both were educated at New Kingswood School, Bath, under Mr. T. G. Osborn. Miss Frost, of Newnham College, was placed between the 24th and 25th Wranglers.

In a recent discussion Prof. Stuart stated that 58 students attended the engineering courses and workshops in the Lent Term. Of these 32 were to be engineers; 7 were to engage in manufactures in which a knowledge of engineering was desirable; 3 were going into the army; 2 were to become teachers. As to their University position, 9 were M.A. or B.A., 21 were ready for the Mathematical Tripos, 2 for the Natural Sciences Tripos, 18 for the Special Examinations in Applied Science; 6 had only come to the University for a year's work in the workshops; 5 were not matriculated students.

DR. ORME MASSON, a graduate of Edinburgh University, and lately Elective Fellow in Chemistry, has been appointed to the Chair of Chemistry at Melbourne, Australia.

SCIENTIFIC SERIALS

Bulletins de la Société d'Anthropologie de Paris, tome ix., fasc. 1, 1886.—The present number gives the usual annual recapitulation of the rules of the Society, the lists of members, addresses by the outgoing and incoming presidents, financial and other reports, &c.—M. Moncelon laid before the Society a *résumé* of the principal results of his observations on the half-castes of New Caledonia during his residence in the colony. He drew attention to the evils resulting from the practice commonly followed by the native mothers of half-castes, of going back with their children to their native tribes, amongst whom these half-whites grow up in slavery as savages.—On certain Hova and Sakalava skulls, by M. Trucy. Both of these cranial groups are dolichocephalic, with an index of about 74, which is nearly the same as that of the Arabs of Algiers and the pariahs of Bengal. The Hovas and Sakalavas appear to be more intelligent than any other tribes of Madagascar, but while the Sakalava queen, the ally of France, submitted with her husband to be made the subject of careful anthropometrical observations, she enjoined upon the French officers to punish with death any one who opened or rifled a grave. It was consequently only by artifice and extreme circumspection that M. Trucy was able to obtain crania or other human bones. In the discussion which followed, regarding the mixed characters of the Hova crania, MM. Topinard, Dally, and others entered warmly into the question of typical and other distinctions of race.—On the development, in the adult, of supernumerary digits, by M. Fauvelle

This paper, which supplies some suggestive and not uninteresting matter, is based upon observations on the abnormal development in a full-grown axolotl of a fifth digit at the base of the fourth, and the gradual reparation, by multiplication of the parts, of various injuries to the other phalanges. Dr. Fauvelle considers at length the conditions on which the formation of supplementary parts in the adult may possibly depend, and whether we may not refer such abnormal manifestations of activity to a reversion in the cells of the connective-tissues to an embryonic condition, in which segmentation is possible. M. Avia, in confirming the views of Dr. Fauvelle as to the influence of heredity in the human species on the appearance of supernumerary organs, instanced the family of the Fodli, which for several centuries had exercised patriarchal supremacy over a tribe of the Arab Hyamites. In this family, whose members are not allowed to marry beyond the limits of their own kindred, polydactylism has become an established hereditary character, and is considered as an indispensable evidence of legitimacy, and right of succession. M. Avia has personally examined various Fodli, all of whom had twenty-four phalanges on their hands and feet.—On heredity, by Dr. Fauvelle. In this, as in the preceding paper, the author draws attention to the injury done to scientific inquiry by the constantly increasing recklessness with which physiological and anatomical conditions, whose causes we are ignorant of, are indiscriminately referred to so-called "atavism." It must be confessed, however, that the author himself in his exposition of the significance of the phenomena of heredity, as given in this paper, and in his more recent communication to the Society of his views regarding the real or assumed existence of atavism, exhibits the same want of accuracy and close definition which he condemns in others, and the vagueness of the opinions which he has enunciated with such dogmatic temerity excited a lively controversy, in which MM. Laborde and Sanson, and Mme. Cl. Royer, with other members, took part.—On primitive forms of numerations, by M. Letourneau. In this paper, and in the discussion which followed its reading, attention was drawn to the development, among some peoples, of a decimal system of numeration from the natural counting of the fingers, while according to Bachofen and others, the decimal method was preceded, in those earlier periods of civilisation in which the matriarchal principle was still in force, by the *octomal* system. Curious evidence of the prevalence of this practice of counting by 8 is afforded in Sanskrit, and in Greek and Latin, as well as in several modern European forms of speech, by the close affinity, if not identity, of the words signifying nine and new, as, *e.g.*, the French "neuf," thus showing that the numeral following eight was of more recent acceptation than the final term of the octomal form of numeration.

Bulletin de l'Académie des Sciences de St. Pétersbourg, vol. xxi. No. 1.—List of the members of the Academy on March 1, 1886.—Diagnoses of new plants from Asia, by C. J. Maximowicz, part 6 (Latin), containing a good many new species.—Report on new linguistic materials contained in the "Codex Comanicus," by Prof. Radloff (German).

SOCIETIES AND ACADEMIES

London

Royal Society, June 10.—"A Minute Analysis (experimental) of the various Movements produced by stimulating in the Monkey different Regions of the Cortical Centre for the Upper Limb, as defined by Prof. Ferrier." By Charles E. Beevor, M.D., M.R.C.P., and Prof. Victor Horsley, F.R.S., B.S., F.R.C.S.

The following investigation was undertaken as prefatory to a research into motor localisation of the spinal cord.

Anatomy.—(1) Attention is drawn to some minute details of the topographical anatomy of the upper limb centres as defined by Prof. Ferrier.

(2) Outlines of the shape and arrangement of the fissure of Rolando, the præcentral and intra-parietal sulci.

(3) Proof adduced in support of the authors' opinion that the small horizontal sulcus named X by Prof. Schäfer really corresponds to the superior frontal sulcus of man.

Previous Researches.—Ferrier's results are then given in full.

Method of Experimentation is explained in detail, as also the mode of subdivision of the part of the cortex investigated into centres of about 2 mm. square.

From the results of excitation are then deduced the two following axioms:—

Axiom I.—Viewing as a whole the motor area of the central cortex for the upper limb, as defined by Prof. Ferrier, we find that the regions for the action of the larger joints are situated at the upper part of the area, *i.e.* closer to the middle line, while those for the smaller and more differentiated movements lie peripherally at the lower part of the area.

Axiom II.—As a broad result, extension of the joints is the most characteristic movement of the upper part of Ferrier's arm centre; while flexion is equally characteristic of the movements obtained by stimulating the lower part. Finally, between these two regions there is a small portion where flexion and extension alternately predominate, a condition to which we have given the name of *confusion*. (Here both flexors and extensors are contracting at the same time, and consequently the joint is usually fixed in a neutral position, each group of muscles alternately drawing it in opposite directions.)

Priority of Movements is found to take place, and follows the "march" first indicated by Dr. Hughlings Jackson as existing in epileptic seizures.

This *march* is in accordance with Axiom I., since the shoulder commences the series of movements in the uppermost part of the area, the thumb at the lowest part, and the wrist in the intermediate part.

Summary.—(1) That X is the superior frontal sulcus of man.

(2) That the movements of the joints are progressively represented in the cortex from above down.

(3) Localisation of sequence of movements.

(4) Localisation of quality of movements.

(5) That there is no absolute line of demarcation between the different centres.

Mathematical Society, June 10.—J. W. L. Glaisher, F.R.S., President, in the chair.—At a special meeting the following resolution was unanimously carried:—"That the Council be empowered to take the necessary steps to obtain a charter of incorporation for the Society."—At the ordinary meeting Messrs. A. R. Forsyth, F.R.S., R. Lachlan, and the Rev. J. J. Milne were admitted into the Society.—The following communications were made:—Reciprocation in statics, by Prof. Genese.—On the theory of screws in elliptic space (third note), by A. Buchheim.—Some applications of Weierstrass's elliptic functions, by Prof. Greenhill.—Formula for the interchange of the independent and dependent variables with some applications to reciprocants, by C. Leudesdorf (second paper on reciprocants), by L. J. Rogers.—On the motion of a liquid ellipsoid under the influence of its own attraction, by A. B. Basset.—Electrical oscillations on cylindrical conductors, by Prof. J. J. Thomson, F.R.S.

Chemical Society, May 20.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following papers were read:—Sources of error in the calorimetric study of salts, by Prof. W. A. Tilden, F.R.S.—On the action of aldehydes and ammonia on benzil, by Francis R. Japp, F.R.S., and W. Palmer Wynne, B.Sc.—On imabenzil, by the same.—On ammonia-derivatives of benzoin, by Francis R. Japp, F.R.S., and W. H. Wilson, Ph.D.—On compounds from benzil and benzoïn and alcohols, by Francis R. Japp, F.R.S., and Julius Raschen.—On the action of phosphoric sulphide on benzophenone, by the same.—The separation and estimation of zirconium by means of hydrogen peroxide, by G. H. Bailey, D.Sc., Ph.D.—An apparatus for the determination of the temperature of decomposition of salts, by the same.—The retention of lead salts by filter-paper, by L. Trant O'Shea.

June 3.—Dr. Hugo Muller, F.R.S., President, in the chair.—The following papers were read:—Notes on Sir W. Fairbairn's experiments on re-melting cast iron, by Thomas Turner, Assoc. R.S.M.—Some ammonium compounds and other derivatives of α-1′ hydroxyquinoline, by C. A. Kohn, B.Sc., Ph.D.—β-sulphophthalic acid, by Prof C. Graebe and A. Rée, Ph.D.—Compounds obtained by the aid of β-sulphophthalic acid, by the same.—Derivatives of taurine (part 2), by J. William James.

Anthropological Institute, June 8.—Mr. Francis Galton, F.R.S., President, in the chair.—The election of Mr. Joseph J. Mooney was announced.—Mr. C. H. Read read a paper on the ethnological exhibits in the Colonial and Indian Exhibition, in which he reviewed briefly the collections to be seen in the various courts, and described in detail some of the objects. The author dwelt especially upon the meagreness of the collection sent from the Dominion of Canada, where there is such a vast

field for ethnological inquiry.—Miss Buckland read a paper on American shell-work and its affinities, in which it was pointed out that the resemblance in shell ornaments found in mounds in various States of North America to those existing in the Solodmon and Admiralty Islands renders it highly probable that a commerce was carried on between the islands of the Pacific anthe American continent prior to the Spanish conquest.—A paper by Mr. C. W. Rosset, on the Maldive Islands, was read. The group contains upwards of 12,000 islands, which lie in clusters called atolls, of which there are more than twenty. The king's or sultan's island is situated in Malé Atoll, and here Mr. Rosset spent seventy days, as the sultan would not allow him to visit the other atolls. The natives live almost entirely upon fish and rice; and as the islands are not capable of producing grain of any kind, the rice has to be imported from India, the nearest point of which is about 350 miles distant. The author gave an interesting description of the customs of the natives, and exhibited a large collection of photographs, dresses, and other objects of ethnological interest.

Royal Meteorological Society, June 16.—Mr. W. Ellis, F.R.A.S., President, in the chair.—The Rev. J. R. Boyle and Mr. H. B. de la Poer Wall, M.A., were elected Fellows of the Society.—The following papers were read:—Note on a sudden squall, January 13, 1886, by Mr. R. H. Scott, F.R.S. This is an account of a remarkably sudden squall of about ten minutes' duration, which passed over the south of England on the morning of January 13. It was first recorded at Falmouth at 8.20 a.m., and passed over London at 10.40 a.m.—The floods of May 1886, by Mr. F. Gaster, F.R.Met.Soc., and Mr. W. Marriott, F.R.Met.Soc. The month of May 1886 will long be remembered for the heavy rains that occurred between the 11th and 13th, and the floods they produced over the greater part of the west and midland counties of England. In fact, at Worcester the flood was higher than any that have occurred there since 1770. On the 11th and 12th heavy rain fell over the east of England, there being over 3 inches during these two days at several places in counties Down, Dublin, and Wexford; the greatest reported being 3·52 inches at Kilkeel, co. Down. Over the other parts of the United Kingdom the rainfall on the 11th was under 1 inch. Rain, however, commenced falling about noon on Tuesday over the midland counties, and continued with increasing intensity till Friday morning; the duration at most places being about sixty hours. The heaviest rainfall occurred in Shropshire, where over 6 inches fell at several stations; while at Burwarton as much as 7·09 inches was recorded, the amounts for each day being 0·60 inches on the 11th, 3·10 inches on the 12th, and 3·39 inches on the 13th Very serious floods followed these heavy rains. At Shrewsbury the extreme height of the flood on the Severn was 16 feet, and at Worcester 17 feet 1 inch, above the average summer level. At Ross the flood on the Wye was 14 feet; at Nottingham the rise of the water in the Trent was 12¼ feet; at Rotherham the flood was 8 feet 5 inches; and in North-East Yorkshire the Derwent rose to nearly 11 feet above summer level. These floods caused great damage to property and loss of life; bridges were washed away; railway traffic suspended; and thousands of workmen thrown idle. In several places the waterworks were flooded, and the towns' water-supply was consequently cut off. Mr. Gaster drew attention to the complex character of pressure-distribution during the time referred to, and showed how the region of maximum rainfall followed certain of the shallow depressions which appeared over the British Islands. He drew attention to the peculiarities of this type of depression, showing how in many, if not in most, cases the rainfall was heaviest in their rear, and was brought by the easterly, not by the westerly, wind. He also referred to some previous instances of heavy floods, in which similar atmospheric conditions prevailed, and explained how it was that, as the disturbance passed off, snow fell instead of rain, this in its turn being followed by severe cold and in some places frost.—On atmospheric pressure and its effect on the tidal wave, by Capt. W. N. Greenwood, F.R.Met.Soc. The object of this paper is to show how a little knowledge of weather-forecasting, with some practical knowledge of local weather changes and a good barometer, will go far towards forming a right correction for application to the predicted height of the tide, and also to determine what that correction should be in its relation to the fluctuations of the barometer and the prevailing gradient.—Meteorological results at Levuka and Suva, 1875-85, with notes on the climate of Fiji, by Mr. J. D. W. Vaughan, F.R.Met.Soc. The climate of Fiji is remarkably healthy. Diseases such as fevers of an aggravated and malarious character, cholera, and liver complaints are unknown.

EDINBURGH

Royal Society, June 7.—The Hon. Lord Maclaren, Vice-President, in the chair.—Dr. H. R. Mill and Mr. J. T. Morison, of the Scottish Marine Station, read a paper on tidal variations of salinity and temperature in the estuary of the Forth. They divide a river-system into four parts: (1) the *river proper* with its tributaries and feeding-lakes, in the whole of which the water is fresh; (2) the *estuary*, in which the river-water meets that of the firth or sea, and in which there is rapid change of salinity with position and great tidal differences; (3) the *firth* or sea-inlet, in which there is a very uniform and gradual increase of salinity from estuary to sea; (4) the *sea proper* adjacent to the mouth of the firth. It was shown that the temperature of the river in spring and summer being higher than that of the firth, and in consequence surface-water being warmer as well as fresher than bottom-water, the curves representing vertical distribution of salinity and of temperature were identical. Hence the interaction of river and firth waters can be studied as completely by the thermometer as by the hydrometer. In the estuary of the Forth translational motion of the whole mass of water is found to characterise both flood and ebb tide, but about the times of high and low water considerable shearing motion takes place. So long as no shearing occurs, the water is of nearly uniform salinity from surface to bottom at any given time.—Mr. J. J. Barlow communicated a paper on a new method and reagents for detecting chlorides, bromides, and iodides in the presence of each other, and also in the presence of nitrates and chlorates.—Mr. J. A. Thomson gave a paper on the anatomy of *Suberites domuncula*, and also, in conjunction with Mr. P. Geddes, a paper on the history and theory of spermatogenesis.—Dr. J. Waddell gave an account of experiments by which he has determined the atomic weight of tungsten. The methods he used are superior to those previously employed.—Mr. A. H. Anglin discussed certain theorems mainly connected with alternants.

PARIS

Academy of Sciences, June 15.—M. Jurien de la Gravière, President, in the chair.—On the earthquake which occurred in Brazil on May 9, extract from a letter of H.M. dom Pedro d'Alcantara. This disturbance, the first on record, took place in the Petropolis district on May 9 at 3.20 p.m. The vibration, which was of a mild character, lasted scarcely four seconds, and was also felt along the coast as far as Rio de Janeiro, and inland 266 kilometres from that point. It was accompanied by exceptional cold weather, the glass falling to -5° C. in some parts of the province of Minas Geraes, and -3° in other places.—On the absorption spectra of oxygen, by M. J. Janssen. In continuation of his studies on the absorption spectra of the gases, the author deals here with those of oxygen, which reveals some features of great interest for molecular mechanics.—Remarks on the decomposition of the sal ammoniacs by the bases and metallic oxides, by M. Berthelot.—On the ammonia present in the ground (third note), by M. Th. Schlœsing, in reply to MM. Berthelot and André. The question is discussed whether the quantity of ammonia present in vegetable soil is, as a rule, comprised between 0 mg. and 20 mg., as determined by the author, M. Boussingault, and other analysts, or whether this quantity ranges from 78 mg. to 118 mg., as determined by MM. Berthelot and André. It is pointed out that the difference between the two views is a question of quantity; and as the quantity depends on the process of analysis by which it is determined, it ultimately resolves itself into a question of analytical processes.—Lavoisier and the Commission on Weights and Measures, by M. E. Grimaux. Some unpublished documents are printed, showing the action taken by the Commission on behalf of Lavoisier, at that time under arrest as a farmer-general. From one of these documents it appears that, in consequence of said action, the illustrious names of Laplace, Delambre, Borda, and others, were themselves removed from the Commission on the 3rd Nivose of the second year of the Republic (December 26, 1793).—Observations on Fabry's comet, by M. L. Cruls. The spectral analysis made at Rio de Janeiro during the month of May with a spectroscope of slight dispersive power showed distinctly the three bands characteristic of carbon compounds.—Comparative dimensions of the satellites of Jupiter, deduced from observations made during the year 1885, by Dom Lamey.

For the four satellites these observations yielded for the vertical diameters at mean distance the following angular dimensions:—

I.	$1''\cdot176 \pm 0''\cdot360$
II.	$1\cdot281 \pm 0\cdot392$
III.	$1\cdot725 \pm 0\cdot436$
IV.	$1\cdot286 \pm 0\cdot447$

—Note on the herpolhodie (second communication), by M. Hess.—On the measurement of the specific volume of the saturated vapours, and on the value of the mechanical equivalent of heat, by M. A. Perot. Reversing the well-known process of Messrs. Fairbairn and Tait for determining the volume of a known mass of saturated vapour at a given temperature, the author finds the number expressing the mechanical equivalent of heat to be about 424.—Note on a registering hygrometer, by M. Alb. Nodon. This instrument, which is constructed on a principle analogous to that of Breguet's metallic thermometer, is contrived to work for ten consecutive days. Its indications are unaffected by a temperature ranging from 10° to 35° C.—Law determining the electric conductivity of saline solutions of mean concentration, by M. E. Bouty.—Relation between the coefficient of self-induction and the magnetic action of an electro-magnet, by M. Ledeboer.—New magnetic maps of France, by M. Th. Moureaux. The observations, which have served as the groundwork of these charts, were mostly made during the years 1884 and 1885 under the direction of M. Mascart, at seventy-eight stations in every part of France, the results being all referred to January 1, 1885, by comparison with the curves of variation as determined with the magnetograph at the Observatory of the Parc Saint-Maur. From these observations the declination is shown to be least at Belfort (13° 59'·8), greatest at Conquet (19° 25'·1), varying in the north of France about 30' for a degree of longitude, and less in the south.—Summer isobars, winds, and cloudiness on the Atlantic, by M. L. Teisserenc de Bort. The maps embodying these data are based on the records of English and Dutch vessels, comprising 40,900 observations for each element, and on a report on the equatorial region published by the Meteorological Office.—Note on the earthquake in Brazil, by M. Cruls. Although traces of ancient volcanoes and more recent eruptive formations have been detected on the seaboard of Rio de Janeiro, the author considers that this seismic disturbance was not volcanic, but due to shrinking or some analogous movement of frequent occurrence in the crust of the earth.—Reply to some objections made to the memoir on microseismic observations, by M. T. Bertelli.—On the penta-sulphuret of phosphorus, by M. F. Isambert.—On the principle of equivalence in the phenomena of chemical equilibria, by M. H. Le Chatelier. The experimental law serving as the base of pure mechanics—two forces equal to a third are equal to each other, and reciprocally—is true also of chemical equilibria. But in order to eliminate the equivocal notion of *force*, the author substitutes for it another thus formulated: in every phenomenon of equilibrium two material systems equivalent in relation to a third will also remain equivalent in relation to any other system to which they may be opposed, and they are in mutual equilibrium when opposed to each other. This law is here verified in the case of vaporisation, dissociation, solubility, and under other conditions.—On monosodic orthophosphate and arseniate, by MM. A. Joly and H. Dufet.—On a combination of methylic alcohol and anhydrous baryta, by M. de Forcrand.—On the monochloracetate of butyl, by M. G. Gehring. In order to complete the series of monochloracetates, the author has prepared, and determined some of the physical properties of, this substance, adopting the same general method as that employed in the preparation of the monochloracetate of methyl.—On the development of the œsophagus, by M. P. de Meuron.—On the vascular system of *Dorocidaris papillata*, by M. H. Prouho.—On the crystals of gypsum in the pseudo-potters' clays of the Paris district, by M. Stan. Meunier.—Preliminary note on the geological structure of the Lure range, Lower Alps, by M. W. Kilian. This range, which runs for 50 kilometres from the neighbourhood of Vilhosc to Monbrun (Vaucluse), appears to be intermediate between the Alpine and Pyrenean systems. A summary is given of its geological constituents, ranging from the Middle and Upper Jurassic to the Tertiary conglomerates and marls.—On the male fertilisations of Arthropitus and Bornia, by M. Renault.—A contribution to the study of pre-foliation and pre-efflorescence in fossil plants, by M. L. Crié.—Remarks on a meteor observed at the Trocadéro on June 13, by M. L. Jaubert.

STOCKHOLM

Academy of Sciences, June 9.—On the Academy's Zoological Station in the province of Bohus, by Prof. Sven Lovén.—On the resistance of mixtures of acids against electrical conductibility, by Dr. S. Arrhenius.—A collection of ethnographical objects of Central American Indians, presented to the National Museum by the Swedish Consul-General in Guatemala, Mr. S. Ascoli, exhibited and explained by Prof. F. A. Smith.—On the new elementary body germanium, and some of its combinations, by Prof. L. Fr. Nilsson. The researches of Profs. Nilsson and Petterson, made at the request of Prof. Winkler, the discoverer of germanium, show that his suggestion that germanium might possibly be identical with Mendelejeff's ekasilicium is quite correct, and in accordance with the true facts.—Methods for the determination of elements of refraction in prisms having great refracting angles, by Mr. W. Ramsay.—On the mode of occurrence of the sand-worn stones in the Cambrian strata at Lugnås, in Sweden, by Prof. A. G. Nathorst.

BOOKS AND PAMPHLETS RECEIVED

"The First Report upon the Fauna of Liverpool Bay and the Neighbouring Seas," Edited by Prof. Herdman (Longmans).—"L'Inclinaison des Vents" R. P. Marc Dechevrens (Chang Hai).—"Die Alchemie in Alterer und Neuerer Zeit," Erster und Zweiter Theil, by H. Kopp (Winter, Heidelberg).—"An Elementary Treatise on Geometrical Optics," 2nd edition, revised, by W. S. Aldis (Deighton, Bell, and Co.).—"Records of the Saidapet Experimental Farm," by Chas. Benson (Keys, Madras).—"New Commercial Plants and Drugs," No. 9, by T. Christy (Christy).—"Bulletin of the Illinois State Laboratory of Natural History," Vol. II., Art. V. "Studies from the Contagious Diseases of Insects," by S. A Forbes (Franks, Peoria).—"Cornell University: Proceedings in Memory of Louis Agassiz and in Honour of Hiram Sibley, June 17, 1885."

KEPLER'S CORRESPONDENCE WITH HERWART VON HOHENBURG

Ungedruckte wissenschaftliche Correspondenz zwischen Johann Kepler und Herwart von Hohenburg, 1599. Ergänzung zu: Kepleri Opera Omnia, ed. Chr. Frisch. Nach den MSS. zu München und Pulkowa edirt von C. Anschütz. (Prag: Victor Dietz, 1886.)

HERWART VON HOHENBURG was a highly stimulating correspondent. His scientific curiosity was insatiable; his official duties as Bavarian Chancellor precluded personal research; and he accordingly deputed to the busy brain of Kepler the working out of problems which engaged his scanty leisure, while baffling his powers. The pressure of his demands was, indeed, so severe that Kepler at times bewailed himself in confidential quarters over the grinding labours they imposed upon him: but he could ill afford to quarrel with a patron who was as generous as he was inquisitive; and he thus continued to evolve for his benefit the stores of curious learning and adventurous theory of which some considerable specimens have lately been unearthed, and are now presented to the public.

The correspondence took its origin from the publication, in 1596, of the "Mysterium Cosmographicum," by which Herwart's admiring attention was drawn to the speculative young "mathematicus" of the Styrian States; and continued from October 1597 to December 1609. There was, however, a gap in its records. Three letters, known to have been written by Kepler to Herwart in the year 1599, were not forthcoming. Dr. Frisch, the late indefatigable editor of Kepler's "Opera Omnia," gave up the search as hopeless; and the detection of the latitant documents became possible only with the correction, in a new printed catalogue of the manuscript collections in the Munich State Library, of an error in the old printed one,—an example, were such needed, of the uses to historical research of the least inviting bibliothecarian drudgery. The opportunity for discovery was promptly turned to account by M. Carl Anschütz, the editor of the present *brochure*; who deserves the acknowledgments of every one interested in scrutinising the workings of a most singularly and brilliantly constituted mind, not alone for the zeal of his inquiries, but also for the elaborate care with which he has set forth their results, rendering intelligible by copious annotations what must otherwise have remained, to the vast majority of readers, hopelessly obscure.

The truth chiefly emphasised by a perusal of these remarkable letters is that of the inextricable entanglement of Kepler's mystical with his scientific views. Many men have speculated wildly while investigating acutely; Kepler alone, perhaps, investigated acutely *because* he speculated wildly. His visions of abstract beauty and order in a neatly fenced and finished universe warmed his fancy, and inspired and lightened labours which would otherwise have been insupportable. His discoveries were the fruit of his illusions, because his illusions were faithfully and unwearyingly confronted with the realities of nature. He was a dreamer; but he was not content to leave his dreams undisturbed by facts. Hence his superiority—

ἔξοχος Ἀργείων κεφαλήν τε καὶ εὐρέας ὤμους—

to the common run of Pythagorean enthusiasts, and hence his great name in scientific history.

The topics discussed in the present correspondence forcibly illustrate the compound nature of his mind, no less visionary in its instincts than positive in its methods. They include the theory of eclipses, the *rationale* of planetary influences, the harmonic relations of planetary velocities, the date of the birth and the horoscope of Augustus, the nature of terrestrial magnetism, and the position, actual and primitive, of the north magnetic pole. The first of the three letters is dated from Gratz, April 9 and 10, 1599. It opens with a pompous eulogium on Tycho Brahe. "Taceant omnes, et Tychoni Brahe Dani auscultent." Nor does it detract, we are told, from his merits to have taken a wrong theoretical turn. His hostility to the motion of the earth nowise impairs the excellence of his observations and instruments. Each astronomer is free to embrace, without discredit to his skill and erudition, whatever "religion of movement" seems best to himself. "Sed ad rem."

Tycho, deceived no doubt by reports of coronal splendours (he had never himself witnessed the phenomenon), had denied the possibility of a total solar eclipse, the moon suffering, he alleged, a diminution of one-fifth of its apparent diameter when projected on the sun. Kepler, while unconvinced of the fact, was at no loss for an explanation. A dense lunar atmosphere, powerfully reflective of the sun's rays, while partially permeable by them, was invoked by him to augment the seeming dimensions of the full moon, and throw a kind of subdued glory round the eclipsed sun. The perplexity started by Tycho was not, however, so easily allayed. It kept cropping up at intervals; and led eventually both to Kepler's optical researches, and to what we may call his discovery of the corona, as an actual fact to be reckoned with by science. The eclipse observed by Clavius at Rome in 1567 he showed to have been unquestionably total; the sun was fully covered by the moon; yet an unlooked-for radiance survived ("Op. Omnia," t. ii. p. 318). He accounted for it by the illumination of an "ethereal substance" in the solar neighbourhood, "not altogether nothing, but possessing some measure of density"; nor have we yet got much beyond the approximate ratification of his conjecture.

Later in life Kepler formally laid down his arms before the lunar theory, after spending enormous labour on the effort to bring it into conformity with his Laws. But here, in these long-missing letters, he unexpectedly emerges as the discoverer of the moon's annual equation. The fact seems to admit of no doubt; his words are explicit. The discrepancies between the observed and calculated times of eclipses compelled the correction. Had not Copernicus, he remarks, been occupied with greater things, he must have introduced the same "annual inequality" depending upon the eccentricity of the earth's orbit. "What he neglected," he adds, "I now do." The chief merit of this important advance has usually been ascribed to Tycho. He had doubtless glimpses of its necessity, but omitted to follow them up. The earliest

explicit declaration hitherto known in favour of introducing such a correction was contained in a letter from Kepler to Bernegger of June 30, 1625 ("Op. Omnia," t. vi. p. 618). It now appears, not only that the conclusion was an entirely original one, but that he had arrived at it twenty-six years previously. M. Anschütz promises some further elucidations of the point, which we await with interest.

One of the most curious chapters in Kepler's mental history is furnished by his attitude towards the astrological superstitions of his time. Herwart, as a good Catholic, had condemned them; his correspondent made out a case in reply. His contention, it is true, was not on behalf of the vulgar charlatanry of the science. This he admitted to be indefensible, save on the one poor plea of stringent necessity. Providence, as he wrote to Maestlin, which had denied to no animal the means of preserving its life, had assigned, for that end, astrology to the astronomer. He must draw horoscopes and publish prophesying calendars, or cease to exist. Thus only could he obtain means to pursue nobler studies. The people, while giving their money for the lies they loved, unconsciously promoted the truth they were indifferent to. It was an involuntary, but none the less efficacious, "endowment of research."

So Kepler filled his empty pockets, and satisfied his conscience by professing incredulity in his own vaticinations. They proved, nevertheless, and, as it were, in his own despite, highly successful. Not a few of them stumbled felicitously into fulfilment. Some art, or luck, drew them, now and again, into conformity with the future. And since, as their author himself remarked, the game is one in which the hits count, but the misses are forgotten ("Das Treffen behält man, das Fehlen aber vergisst man") his reputation as a seer rose high, and brought him in the best and only sure part of his income.

There was, however, a recondite species of planetary influence believed in by Kepler as part of the eternal order of things. By the belief, indeed, his whole career of investigation was profoundly influenced; for the effort to justify it led him into a track of thought which finally conducted him to the Third Law. One of the chief points of interest in the present correspondence is that it discloses the time and manner of his entrance upon that track. "Lift up your ears to listen: Eureka!" he wrote to Maestlin, August 29, 1599; and to Herwart, August 6, he solemnly announced his invention of a "theorema jucundum," in which was concentrated the whole secret of the music of the spheres. Already he gives the title ("de Harmonia Mundi"), and, to a certain extent, the plan, of the great work published twenty years later. It was conceived, as we now see with additional clearness, less under the influence of sober truth-seeking, than in the fervour of illusive speculation. Essentially, it was a piece of brilliant extravagance. That the harmonic law of periods and distances should have been found as a nugget amid such worthless, though shining debris, is one of the oddest facts in the history of science.

The theory of planetary harmonies was struck out by Kepler as an adjunct to his peculiar theory of planetary aspects. It might in fact be called its dynamical counterpart. Geometrical relations of movement were substituted in it for geometrical relations of position. The velocities of the six planets were, he averred, so connected that, were there an inter-planetary medium capable of conveying audible vibrations, a celestial chord of the sixth and fourth would perpetually resound through space. The intellectual perception of potential harmonies sufficed, however, for the delectation of the rational creatures appointed to enjoy them; while, similarly, the intellectual apprehension of "aspects" affected, primarily, the sentient "soul of the world," and, secondarily, through the varying moods thus impressed by the stars, the course of sublunary affairs. The third letter to Herwart is mainly filled with details of Kepler's persevering efforts to complete and fortify the visionary analogy between astrological aspects and musical intervals.

Yet even here, in this region of intangible speculation, his innate respect for facts did not desert him. What autobiographical details he left, we owe to his desire to compare his life as it was with what, astrologically, it ought to have been. And the first of the present letters contains a highly curious little bit of self-study, illustrative of the depressing effects of "Saturn in sextile with the Sun" at the hour of nativity. Here is Kepler described by himself, ætat. twenty-seven.

"A body of no ample proportions, lean and scraggy; a mind unaspiring, that is to say, burying itself in literary nooks and crannies, suspicious, timid, tending towards, and abiding in difficulties and knotty points; manners to correspond. Sour and sharp flavours, the gnawing of a bone, the devouring of dry bread, form my gustatory delights; my keenest ambulatory joy is to traverse steep and rugged paths, to mount hills, to pierce my way across dense thorn-brakes. Pleasure in life other than in study I neither have nor desire; proffered, I reject. My fortune matches my tastes to a hair. Where others might abandon hope, I find access to achievement and fame. Yet not over spacious; for my advance is continually checked, and my circumstances change without mending. All my efforts have hitherto met with strenuous resistance. It may be that social sympathy will ever be denied me while I irritate mankind by advocating the movement of the earth, while

> Obnixa cervice cito per sidera lapsu
> Incito, terricolûm contra nitente senatu."

A. M. CLERKE

UPLAND AND MEADOW

Upland and Meadow, a Poactquissings Chronicle. By Charles C. Abbott, M.D. (London: Sampson Low, Marston, Searle, and Rivington, 1886.)

THIS is a very pleasantly written book by an author who may be justly regarded as a kind of American Gilbert White. We may as well inform our readers at once that the district of which the natural history is herein chronicled is situated by a little stream which empties itself into the River Delaware, and that the name, which will appear to English readers somewhat difficult of pronunciation, is of Indian origin. There are fourteen chapters in the work, and an index which is to be strongly commended for its completeness. It is really a most important feature in a book of this kind to have a good index, and in insisting upon this necessity we are intentionally paying a complimentary tribute to the

author, because there is a large amount of valuable observation which readers should have occasion to refer to after the first perusal of the work, but which would be lost without such an index, owing to the necessarily disjointed mode of treatment entailed by an adherence to seasonal records. We need only refer to the early editions of Kirby and Spence's "Introduction to Entomology" as an example of a work containing a large collection of facts and observations rendered almost useless for want of an index.

Dr. Abbott is evidently a close observer, and English naturalists will derive both pleasure and profit by a perusal of his chronicle. It is rather to be regretted that he has confined himself so much in the text to the local trivial names of the animals and plants of his district. It places English readers at a disadvantage, for example, to have to turn to the index each time a species is mentioned in order to find out what is referred to under such names as "grakles," "quaker-girls," "quahog," or "scuttle-bug." But this is, after all, a matter of small importance, because the scientific names will be found in the index, and the criticism is made only on behalf of that large circle of readers in the old country which the work ought to attract, and to which it appeals through its English publishers.

The author's strong point appears to be ornithology, but his sympathies are fairly distributed, and his observations are recorded in a pleasant, chatty style which is sure to be attractive to general readers :—

"To realise what a wealth of animal and vegetable life is ever at hand for him who chooses to study it, let a specialist visit you for a few days. Do not have more than one at a time, or you may be bewildered by their enthusiasm.

"I have had them come in turn—botanists, conchologists, microscopists, and even archæologists. What an array of names to strike terror to the breasts of the timid; yet they were all human, and talked plain English, and, better than all, were both instructive and amusing."

As a specimen of the author's style we give the following from Chapter II., entitled "Poaetquissings in Winter."

In order to carry on observations without frightening the denizens of the creek, the author was in the habit of lying down upon the ice, covered over with a blanket so as to be able to see into the frozen depths. The terrestrial life soon became accustomed to his presence, and at length became inquisitive. "This was amusingly illustrated in one instance by a weasel, in crossing the creek on the ice, stopping to investigate the peculiar something lying in its path. Peering under the blanket, it either heard my blood circulating or smelled it. At all events it gave my ankle a nip which brought me quickly to my feet, and sent the bloodthirsty wretch scudding over the ice with marvellous rapidity. How the crows laughed! I had noticed a flock of these birds when I went to the creek, and had been wondering if their incessant cawing was not a discussion of my curious movements. They were, possibly, disposed to think me a trap laid for them, but were astonished or amused at my sudden regaining of the perpendicular when the weasel offered to investigate the matter."

In the third chapter, "Twixt Cold and Heat," will be found a good collection of observations and experiments bearing on the subject of instinct, with special reference to the nesting of birds. Whether the author's views on this much-vexed question will command assent we cannot undertake to say, but whether we differ from his conclusions or not, his experiments are certainly worthy of serious consideration. Among these we have a series of experiments with a chromo-picture of a cat, with a mirror, and with coloured yarns, the latter having for their object the testing of the sense of colour. In the case of a Baltimore oriole in course of building its nest, a decided choice was exerted—red, yellow, purple, and green yarns having been refused, and gray only selected, till the nest was nearly finished, when a few of the purple strands were used. Other amusing experiments on the transference of eggs are described in this same chapter.

With reference to the subject of migration the author states in Chapter IV., on "Marsh Wrens," that "temperature and migration are largely coincident, but cannot be considered as cause and effect." He further adds that certain rules respecting the habits of American birds which had been regarded by previous observers as fixed and invariable, are quite variable if observations are only continued over a sufficiently long period of time. "The results of a single year will have but little bearing upon the regularity or want of it in a bird's movements. The observations of the same person in the same locality must extend over at least a decade before it is safe to arrive at any general conclusions." We commend this passage to the members of our county field clubs who are in want of material for observation.

Space will not permit us to make any lengthy extracts from the book, but we cannot refrain from calling the attention of the bird-destroyers of this country to the admirable "apology" for the grakle (*Quiscalus versicolor*) which the author makes in the fifth chapter. These birds were formerly regarded as enemies to agriculture, owing to their habit of feeding upon ripe grain, which led to their being dubbed by the unpopular name of "maize thieves." But, according to Dr. Abbott's observations, it is at least doubtful whether, on the whole, man does not profit more by the existence of these birds than is lost by the attack upon the grain. To get an idea of the amount of insect food consumed by a pair with five young, he observed the birds for two hours (10 to 11 a.m. and 2 to 3 p.m.), during which time thirteen trips were made by each bird, each returning with an insect every time. The young thus got a "square meal" at least every ten minutes. The feeding goes on for ten hours per diem till the young are twenty-five days old, when they leave the nest, so that during this period each young bird has been supplied with 1300 insects, or 6500 altogether. The eleven nests in the colony under observation were supplied, therefore, with 71,500 insects, and as seven pairs in the colony raised second broods, a further supply of about 45,500 insects was "requisitioned," thus bringing up the total number consumed by one colony of birds to the enormous total of 117,000, or, including the food of the parent birds, about 150,000 "forms of insect life destroyed, all of which would have proved more or less destructive to the growing crops." We hope that the lesson taught by this observation will not be lost upon those who fail to see in persecution by birds a sufficient

cause for the marvellously perfect cases of adaptive resemblance so common among insects.

Apropos of the extermination of plants, Dr. Abbott remarks (p. 41) with respect to the witch-hazel (*Hamamelis virginica*):—"Bent twigs of this plant are still used by the 'gifted' to find water, lost farming tools, and, by one enthusiast, Indian graves. The faithful still claim it as efficacious, and he who doubts is sneered at if he expresses his opinion. All that the rambler can ask is that the plant be not exterminated, and that the fools may be." We may perhaps echo this sentiment on this side of the Atlantic without offence to the members of "Primrose" or any other floral "Leagues." A protest against the extermination of rare plants by "dealers" was circulated by the Corresponding Societies Committee of the British Association last year.

We have given a sufficient idea of this work to commend it to the notice of English naturalists, and we may remark in conclusion that, although the animals and plants referred to are not familiar to the ramblers by our own streams, the sparkling anecdotal style will cause the volume to be enjoyed by all, whether trained observers or casual country wanderers, and the spirit in which the author goes forth into the fields and woods or saunters by his favourite "Poaetquissings" may be well imitated by the numerous field naturalists now being called into activity by the widely-spread establishment of local societies. "He who has this interest in the life about him can never be lonely, wander wheresoever he will, nor return from a contemplative ramble other than a wiser and happier man." R. M.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On Refractometers

I OBSERVE that in your issue of June 17 (p. 157) there is an article by Mr. Gordon Thompson on "The Determination of the Index of Refraction of a Fluid by Means of the Microscope." The method there described was, I believe, first proposed by the Duke de Chaulnes in 1767; and in 1876 was suggested by Dr. Royston Pigott in connection with his refractometer. It was employed in 1878 by Dr. Sorby for recognising the minerals in thin slices of rocks; and in 1884 by Dr. Bleekrode in determining the refraction of liquefied gases (*Proc.* Royal Society, vol. xxxvii. p. 343). In these two instances the ordinary method was unavailable. The proposed method has not been much used owing to the fact that the index of refraction cannot be at all depended upon beyond the third place of decimals.

Mr. Thompson considerably exaggerates the difficulty of the usual method by means of a hollow prism: the angle of the prism may be determined once for all; the position of minimum deviation presents no difficulty; and the use of monochromatic light is unnecessary. Indeed it would be objectionable, as it would prevent the determination of the dispersive power, which is often of equal importance with the refractive power of the substance. In my own experiments I have often taken observations both of the refraction and dispersion of five or six liquids during the course of an hour, including the cleaning of the prism between each.

The suggested method seems scarcely to admit of determining the temperature of the drop with any accuracy, which is an important matter where liquids are concerned. It may, however, doubtless be employed by those who have a good microscope, where great accuracy is not required.

There is an instrument called Abbe's refractometer, which I have recently used for preliminary determinations, and I find it gives accurate results to the third place of decimals. It is founded on the principle of total reflection. It requires also only a drop of the liquid, and as the index of line D is read off without any calculation a complete determination can be made in a minute or two. There is also an arrangement by which the dispersion D to F can be observed and calculated, but I do not find that this is accurate enough to be of much service. The instrument is to be obtained of Carl Zeiss of Jena.

17, Pembridge Square, June 26 J. H. GLADSTONE

Luminous Boreal Clouds

DURING the past two or three years what appears to the writer a distinct class of luminous night clouds in the north sky have occupied his attention. They have probably not escaped more competent observers, and been perhaps referred to simple auroral phenomena, thus escaping discussion. A very marked example was visible here the night before last (22nd inst.), of which inclosed is an illustration from a sketch at the moment.

I may premise the sky was generally clear, stars bright, temperature very low, and wind strong (N.B.) from north-west—a direction maintained for the past two days. Only a slight degree of illumination was imparted to the clouds by a low moon in the south-east, near last quarter. Some light cirrus "scud," high up, conformed to direction of wind.

Above and behind a dark but very limited bank of strato-cumulus, a luminous cloudlet of brilliant pearly lustre appeared, not concurrent exactly with either the magnetic or true meridians, in altitude from 5° to 10° from the horizon, and for 7° in horizontal arc. Its shape, character, and position little varied during observation from 11.30 p.m. to 2 a.m. The structure in this case (only partially realised in the sketch) was striated, the "strike" of main streaks being north-east and south-west. *Transverse bars of luminosity conformed closely to the direction of the cirrus clouds above, and of the wind.* On the three or four other occasions of such observations these luminous cloudlets have been devoid of structure, but in every case they have presented, as in this, an opaque pearly lustre, with definite outline.

Of an entirely different type to the eye are the sudden, diffuse, variable, and transient transparencies of auroræ. Avoiding premature discussion, one cannot but suspect the former occur in much lower and less rare sky-tracts probably than the latter, with a possible frictional factor in their development; and might be distinguished as *nub culæ boreal.s* if accorded a special place on further observation. The temperature has been keeping low, and sunset after-glows have in some degree reappeared during the past week; especially gorgeous being the cloud-tints at sunset of the 22nd inst. D. J. ROWAN

Dundrum, co. Dublin, June 24

Ampère's Rule

WITH regard to Ampère's rule I should be glad to know what is the general experience of actual teachers?

I have taught electricity to boys for four years, and when at Rugby I learned the subject for I think two years. My experience has been that "Ampère's rule" is *not* confusing; and as a teacher I find it best to give both this rule and the "screw-motion" rule. I see that Mr. Cumming gives both, on p. 222 of his book. W. L.

The College, Cheltenham

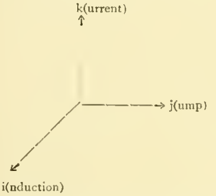
As Prof. Daehne (NATURE, June 24, p. 168) has called attention again to the treatment of Ampère's rule in my "Electricity Treated Experimentally," perhaps you will allow me to point out that the rule given by Ampère is quoted *historically* only, and for it is substituted a rule, due, I believe, to Clerk-Maxwell, which seems to me preferable to either the original rule of Ampère, or to that quoted by Prof. Daehne, namely, that the movement of a north pole is right-handed to the direction of the current. That is to say, if we assume any right-handed screw to be propelled along the current, the north pole will move in the direction of the twist in the muscles of the wrist in propelling it; and *vice versâ*, if the north pole move in

the direction of propulsion, the current urging it will be in the direction of twist in the muscles of the wrist. In treating the movement of a conductor carrying a current in the magnetic field, I have used a rule identical in character with Ampère's, and that was probably the rule to which J. T. B. referred in his critique, namely, that a figure swimming in the current and looking along the lines of force is carried to his left. I should be glad to find a rule at once as complete and more simple, although after a pretty wide experience, not always with the very brightest of pupils, I have not been sorely pressed with the difficulty J. T. B. seems to have felt. All the required attitudes are pretty familiar to a boy who is accustomed to diving in the water and swimming on his front, side, or back. L. CUMMING

Rugby, June 24

THE following version of Ampère's Rule is one which I communicated some time ago to a few friends, but it did not appear to me to be expressed in language sufficiently grave to justify its publication. Still, as the Rule is a simple and useful one, your readers, in general, may be disposed to overlook its levity.

Draw the three well-known Hamiltonian vectors, i, j, k. After i put (nduction), after j put (ump), and after k put (urrent). Then the figure explains the action of magnetic induction on an electric current. The figure in fact asserts that i(nduction) in i makes k(urrent) in k to j(ump) along j.



Of course the same figure gives the direction (according to the Law of Lenz) of the current generated by a motion (*i.e.* a jump) of a conductor in a given direction in a magnetic field in which the direction of the induction is given.

R.I.E. College, Cooper's Hill GEORGE M. MINCHIN

An Earthquake Invention

IN my letter to NATURE, vol. xxxiii. p. 438, I clearly showed that the supposition of Mr. D. A. Stevenson and Prof. Piazzi Smyth that I had endeavoured to claim the aseismatic joint of Mr. D. Stevenson was due to their imperfect acquaintance with seismological literature. I certainly intercalated a *note* about aseismatic structures in a report to the British Association on earthquake phenomena in general, without mentioning Mr. Stevenson's name.

Previous to this, when specially speaking or writing upon aseismic structures, I have *repeatedly* referred to the work of Mr. D. Stevenson. Such references were quoted. Under the circumstances I asked Messrs. Stevenson and Smyth to distinctly state whether they still considered themselves justified in continuing their accusations. If this point was overlooked the discussion might be considered as at an end. Mr. D. A. Stevenson has replied, but the question at issue *has been distinctly evaded* (NATURE, vol. xxxiii. p. 534).

I deeply regret that Messrs. Stevenson and Smyth should allow a discussion to terminate in such a manner.

Tokio, May 22 JOHN MILNE

[This must now close.—ED. NATURE.]

Professor Newcomb's Determination of the Velocity of Light

I HASTEN to correct an error which has crept into my account in last week's NATURE (p. 171) of Prof. Newcomb's measures of the velocity of light. The arrangement employed by Foucault in 1862 was *not* that adopted by Newcomb, and illustrated in Fig. 1, but that sketched in Fig. 2. In other words, he placed his lens between the revolving and fixed mirrors. His apparatus is described in *Comptes rendus*, t. lv. p. 792, where the velocity of the rotating mirror is stated to have been 400 revolutions a second, and the total length of path between the mirrors 20 metres. Solar Halo and Sun Pillar seen on June 5, 1886

WHEN approaching the Observatory, about 6.45 p.m., my attention was drawn to portions of a solar halo, which appeared as in Fig. 1.

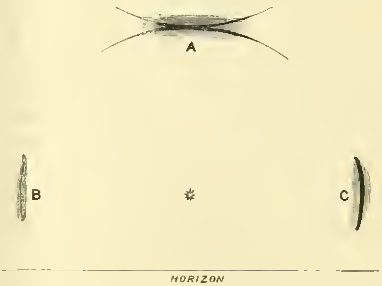

FIG. 1.—A, very bright; C, fainter; B, very faint.

This remained visible until after 7 p.m., and nothing more was seen before 7.30 p.m. When looking out at 7.40 p.m. G.M.T., I noticed something unusual, and came at once to the conclusion that it was a solar pillar, and made a sketch in a note-book and the following remarks:—

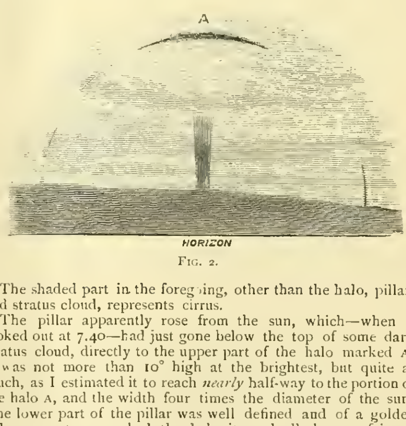

FIG. 2.

The shaded part in the foregoing, other than the halo, pillar, and stratus cloud, represents cirrus.

The pillar apparently rose from the sun, which—when I looked out at 7.40—had just gone below the top of some dark stratus cloud, directly to the upper part of the halo marked A. It was not more than 10° high at the brightest, but quite as much, as I estimated it to reach *nearly* half-way to the portion of the halo A, and the width four times the diameter of the sun. The lower part of the pillar was well defined and of a golden colour; as it approached the halo it gradually became fainter, and was then lost in the cirrus cloud. The upper part was somewhat wider; perhaps this was due to the greater amount of cloud there, which diffused the light.

At 7·55 G.M.T. all portions of the halo had gone except a small piece at A, and the pillar was fainter, but still quite visible. At 8·3 the halo and pillar had disappeared. The sun set at 8·14 p.m.

An ordinary halo ($22\frac{1}{2}°$) was visible, more or less bright and complete nearly from sunrise to sunset.

I could not fix the position of the pillar by stars, none near being visible. The sketch was made at the time from a window of the library of the Observatory.

That seen here on 1883 April 6, by Mr. W. A. Robinson, was about 15 minutes *after* sunset; this observation was 30 minutes *before*. The time at which the pillar was visible on the former date was given by nearly all your correspondents as

15 m. to 45 m. *after* sunset, and in most cases in a cloudless sky; but that on 1886 June 5 was the reverse in both points. Some notes will be found in NATURE, 1883, April and May, for the pillar observed in that year. That seen here partly resembles Fig. 4, Plate III. in *Symons's Meteorological Magazine*, 1871.

F. A. BELLAMY

Radcliffe Observatory, Oxford, June 21

The Enemies of the Frog

WHEN living at Mackay, Queensland, I frequently observed that the common house-frogs (*H. cærulea*) were injured in the hind-limbs, and on several occasions I would hear them croaking in pain; but on arrival all I saw would be a wretched exhausted frog weakly hopping away with a wound in the hind-leg, from which the blood would be oozing. Later on I found that rats attack the frogs. The rats catch the frog by the hind-leg, and apparently suck the wound they cause, then let the frog crawl away, attack it and suck it again, and so on until the rat has had enough. I believe the rats suck the blood, because I was never able to discover a frog so attacked on which the flesh had been destroyed.

Mr. W. P. Fletcher, a well-known local naturalist, once gave me the following account of a mantis attacking a frog. It was in the autumn of 1877, at Rockhampton, Queensland. He was "attracted by hearing the noise of a frog in distress, in the daytime, in some garden-shrubs about 6 feet high; he went to see the cause, and found a green frog about 2 inches long. A green mantis about 5 inches long, with one claw had hold of it across the neck, so that the frog could not move, and the mantis was chewing, and did chew off, the hind-leg, the blood flowing profusely." He called Mrs. Fletcher to see them, and then destroyed the mantis, whereon the frog crawled away.

At Lake Elphinstone (100 miles from Mackay) I once found a small frog (*H. rubella*) in the house in a very exhausted condition; on examination I found a large leech on its tongue. This specimen, with the leech attached, I gave to Mr. Boulenger at the British Museum, where it can be seen.

At Mackay the chief enemies of the frogs appeared to be the snakes and the *Agamidæ*.

H. LING ROTH

Chronology of Elasticians

IN forming a chronological list of writers on elasticity I have been unable to ascertain the following dates, which I should be much obliged if any of your readers would kindly supply: Mariotte (*né près de Dijon vers* 1620, Marie). Is nothing more definite known as to the date of his birth?

F. E. Neumann ... ... W. Weber ... ... Eaton Hodgkinson	Death years.
S. Haughton ... ... J. H. Jellett	Birth years.

University College, London, June 27

KARL PEARSON

SOLAR METEOROLOGY[1]

SIG. TACCHINI'S detailed report on the various phases of solar activity during the year 1884 deserves, as might be expected from the reputation of its author, most careful attention. Exceptionally fine weather permitted observations of sunspots and faculæ to be made at the Collegio Romano on 307 out of the 365 days, so that the materials accumulated were more than usually abundant. We are thus particularly well informed regarding the symptoms attending the protracted maximum which culminated in February 1884.

This is the more fortunate as that maximum was distinguished by features of special interest. It was delayed considerably beyond the usual term, the interval from the maximum of 1870 being no less than 13·4 in lieu of the normal 11·1 years. And to this delay corresponded a greatly reduced intensity, in accordance with the law by which the undulations of the curve representing spot-frequency are low in proportion as they are long. The maximum of 1884, accordingly, was by much the feeblest which had occurred since 1830. It was moreover a hesitating—it might almost be called an abortive—maximum. Some unknown cause apparently interfered with its due and punctual development. Partial anticipatory outbreaks betrayed the tendency, continually repressed, to complete the cycle at the regular epoch, and with the regular expenditure of energy. Now perturbation—of whatever nature—is always instructive: hence Signor Tacchini's laborious statistical results acquire added significance.

They have been gathered along several closely connected lines of research. The various classes of solar surface-phenomena—spots, faculæ, prominences, metallic eruptions—have been studied apart, and the several resulting inferences as to the progress of solar disturbance subsequently confronted. The trifling discrepancies thus revealed show the mutual dependence of no two such species of commotion to be absolute. Each swells or subsides on the whole without immediate or invariable reference to any other, although under the obvious control of some common underlying cause.

Sunspot activity received a notable accession in the beginning of October 1883, the phase of excitement reaching its acme in the following February,[1] and persisting until the end of May. Since then, some slight oscillations notwithstanding, it has continually declined. The sun was not, however, observed at Rome to be free from spots on a single day in 1884. The maximum for prominences occured in March, and they continued exceptionally numerous down to the end of October. In all, 2714 were delineated and described in 242 observations with the spectroscope, being at the average rate of 11·22 per diem. Sixty metallic eruptions, observed on the same occasions, gave a mean diurnal frequency of 0·248 as against 0·171 for 1883. The richest crop was collected in November 1884, during which month ten eruptions were recorded in sixteen observations. The development of faculæ deviated so markedly from that of spots that their respective fluctuations were at times even inverted. It should also be noted that the mean area per spot in 1884 was of little more than half its value in the preceding year, and that the magnetic instruments at Rome remained throughout comparatively calm

Much valuable information is afforded by Signor Tacchini's careful inquiries as to the distribution on the sun's surface of the different orders of solar phenomena. All these showed, during 1884, a conspicuous prevalence of activity in the southern hemisphere; and the inequality—as appears from a note by the same author presented to the Reale Accademia dei Lincei, March 7, 1886—became still more striking in the ensuing year. No spot was observed in either hemisphere during 1884 at more than 30° from the equator; nor on the northern side, during the latter half of the year, at above 20°. With this contraction of the spotted zone coincided a close approach to the equator of the parallel of maximum frequency; and the usual equatorial minimum was both in 1884 and 1885 very imperfectly maintained.

Prominences were plentifully distributed between 60° north and 50° south latitude, with maxima between 20° and 30°. As during the spot-maximum of 1870, they showed no disposition to avoid the vicinity of the equator; while in 1880, 1881, and 1882, the equatorial minimum of prominences was very marked, and remained perceptible in 1883. Although some rare instances of metallic eruptions were detected in high northern latitudes, they affected chiefly a zone bounded by parallels of 20°. Faculæ occurred predominantly in the same region, and nowhere appeared in latitudes above 50°. On the whole, a concentration towards the equator of the whole range of phenomena was unmistakable, and might be thought to

[1] M. Rudolf Wolf places the maximum in November 1883.

correspond with a more advanced stage of the spot-cycle than was indicated by numerical data alone.

Signor Tacchini concludes his memoir with a survey of the vicissitudes of spot-formation during eight years—from January 1, 1877, to December 31, 1884. The results are graphically exhibited in a set of curves variously derived. No. 1 is constructed from the daily numbers of spots with their accompanying pores; No. 2 from the record of spots alone; No. 3 shows the frequency of groups; No. 4 follows the fluctuations of spotted area; No. 5 those of facular extension. All the first four methods agree in fixing the ab olute minimum in March 1879; Nos 1, 2, and 3 display secondary maxima in September 1880, March and July 1881, and March 1882: the absolute maximum was reached, judging by the statistics of spots and groups (curves 2 and 3) in February 1884; but in November 1883, according to those of spots with pores, and spotted area (curves 1 and 4). It is noticeable that the preliminary maxima are largely exaggerated in proportion to the true maximum, when pores are admitted into the account with spots; while the curve resulting from the simple enumeration of groups is very slightly indented. This last method is regarded by our author as that which should invariably be followed when recent have to be compared with ancient records of sunspots; but no system of observation with the eye can any longer compete with the simpler and surer one of photographic registration.

The curve of facular extension for 1877–84 is somewhat anomalous. It touched its lowest point in November 1878, five months previous to the spot-minimum, then sprang up to an absolute maximum in October 1880. This was followed by a secondary but very considerable rise in September 1881, after which, during two years, a tolerably high average level was maintained. The definitive decline which set in in September 1883 was only partially arrested in May 1884. The coincidence between the maximum of faculæ in September 1880, and a large and abrupt increase in the formation of pores, just a month earlier, should not be overlooked. It is also remarkable that a maximum of prominences, but slightly inferior to that of 1884, occurred in 1881.

The condition of the sun in 1885 is epitomised in the note by Signor Tacchini already referred to. That year was, in his opinion, distinguished as one of continued agitation by the persistent abundance of its various symptoms in the neighbourhood of the equator. A zone of 40° north and south covered all the spots, and (save one example of each kind) all the faculæ and metallic eruptions observed. The tranquil or "hydrogenic" description of prominences, on the other hand, figured indifferently in all latitudes. Their general equality of diffusion was but slightly infringed by a southern preponderance; while the frequency in the same hemisphere of spots, faculæ, and eruptions was, in each class, almost double that of its northern occurrence. The alternating activity of the solar hemispheres, thus exemplified in one of its most conspicuous phases, is one of the many enigmatical features of solar disturbance.

SEISMOLOGY IN JAPAN[1]

FOUNDED only in 1879, the Seismological Society of Japan is already able to point to a good record of accomplished work. The Society was happy in the time and the place of its birth. No home could be more fitted to nurse the enthusiasm of the seismologist than one whose foundations are shaken, on the average, a little oftener than once a week. One may take a rather half-hearted interest in other natural phenomena, but, while it lasts, an earthquake certainly commands undivided attention. And the Society came into being just when a few zealous investigators were striving who should be first to solve the problem of obtaining an accurate record of how the ground moves in an earthquake. Lord Byron has described a thunderstorm in the Alps as the joy of the hills "o'er a young earthquake's birth;" but the joy of the hills, if more loudly expressed, was nothing like so deep as the joy with which the inventor of a new "earthquake machine" felt the first convulsion that came to test its powers. In these congenial conditions it is not surprising that the Society's early volumes record the history of what is nothing less than a new departure in observational seismology. Of late the Society has suffered by the removal from Japan of some of its more active members; but this latest volume of its *Transactions* gives satisfactory evidence that, while it has not yet lost all its foreign supporters, some of the Japanese themselves are ready to step forward and continue the work. So long as Prof. Milne remains, the Society will not lack material for publication; the present volume, like many of its predecessors, is largely the work of his pen.

The first paper, on "Seismic Experiments," is by Mr. Milne, and contains an account of eight series of experiments on artificial earthquakes, as well as some laboratory work. Part of this work was done in conjunction with Mr. T. Gray, and much of it has already been described in other papers. The vibrations of the ground were produced in some instances by letting fall heavy weights, in others by the use of dynamite. Several observing-stations were selected, at various distances from the source of disturbance, and generally in one straight line with it. At these stations seismographs of various kinds were placed, and Prof. Milne seems to have preferred the horizontal pendulum seismograph of the present writer as an instrument for recording separately two rectangular components of the horizontal motion of the ground. By placing the pair of pendulums so that one recorded vibrations in the direction of the line joining the station with the source, while the other recorded vibrations at right angles to this, Prof. Milne was able to separate without difficulty the normal from the transverse constituents of the disturbance, and to see the normal vibrations arrive sooner than the transverse vibrations at each station, as the theory of waves in elastic solids requires. In this instrument the two components of horizontal motion are separately recorded on a moving plate of smoked glass. Another instrument was used to record the whole horizontal movement on a fixed plate, and, as might be expected, the diagrams it gave showed first a movement in the line of the source, quickly followed by a confused wriggle of vibrations in all azimuths. By telegraphically connecting the moving plates of the horizontal pendulum seismographs, Prof. Milne endeavoured to determine the interval of time between the arrival of the disturbance at successive stations, and so to infer the velocity of transit. From the results he has concluded that the velocity decreases as the disturbance travels away from the origin, but the figures on which this conclusion is based seem to the present writer to furnish very insufficient evidence. In one series of experiments there is, in the average of three pairs of observations, a loss of about 6 per cent. in the velocity between the second and third stations as compared with the velocity between the first and second stations; but, when we examine the individual observations, we find in one case a gain of velocity amounting to 14 per cent. And, on turning to what is apparently the most complete series of automatically-recorded diagrams (which are reproduced in lithographed plates), it is clear that the time-intervals cannot have been measured with the precision necessary to establish this result, still less to justify the further conclusion that the velocities of normal and transverse waves become more nearly equal as the disturbance spreads. The velocity of transit is, in fact, a term of very vague meaning, unless we can follow an individual wave along its course. As Mr. Milne's

[1] *Transactions* of the Seismological Society of Japan, vol. viii. (Tokio: Published by the Society, 1885.)

own observations show, the shock loses much of its individuality as it travels further from the source. It becomes more and more preceded by a vanguard of small waves, and, for this reason, seismoscopes of different degrees of sensibility will differ in the time at which they chronicle the arrival of the group. Mr. Milne's results, as summarised by him at the end of the paper, are too numerous to be taken up in detail. The assiduity with which he has pursued these experiments deserves the greatest praise, especially as the experiments themselves are of a very high order of difficulty. It is perhaps to be regretted that Mr. Milne has not given his attention more to perfecting a single series than to multiplying results which, as he himself remarks, are often "most discordant." Seismographs will not tell the truth unless they are very well made and very carefully tended. Some of the jagged outlines of the curves are much more likely to be due to friction and shakiness and want of rigidity in the instruments than to any characteristic in the motion of the ground; and unless the lithographer has done Mr. Milne a serious injustice, there are cases where the ground suffers a considerable displacement in a good deal less than no time. He has himself observed this in one instance, and ascribes it to what must (if his explanation be correct) be called a faulty mode of setting the seismographs. It is not impossible to get results free from these defects; and a single really good set of diagrams would do much to remove the uncertainty which now attaches to many of Mr. Milne's results.

Besides the experiments with artificial earthquakes, the paper describes a laboratory investigation of the stability of cylindrical columns standing on a platform which vibrates horizontally, and of the velocity of projection of detached bodies. The projected bodies were balls, held in L-shaped notches at the top of a vertical wooden post; the post, bent slightly to begin with, was allowed to spring; the velocity of projection of the ball was determined from its trajectory, while the greatest velocity of the post-head was measured by means of a revolving plate of smoked glass. The two agreed fairly well, and with a nearly frictionless ball supported in this manner no other result was to be expected. The late Mr. Mallet used to calculate the velocity of the ground's motion from observation of the horizontal distance traversed by projected bodies, but the velocity with which a body is projected depends too largely on the mode of support, and on the amount of adhesion between the body and the support, to allow the result to be, in general, of the slightest value. With regard to the overthrow of columns, it would seem that the author falls into the error of supposing that when the resultant force got by compounding the weight of the column with its resistance to acceleration passes outside the base, the column will fall. But since the disturbing force is of short duration, all that necessarily happens in such a case is that the column will rock; whether it will fall or not is a question of much greater difficulty.

The second paper is a note by Mr. S. Sekiya, "On Prof. Ewing's Duplex Pendulum Seismometer, with Earthquake Records obtained by it" The paper is a brief but very clearly written account of a form of the duplex pendulum seismograph designed by the present writer in 1883, and now in constant use under Mr. Sekiya's care. An earlier form of the instrument has already been described in NATURE (vol. xxx. p. 152): the latest modification of it was exhibited to the British Association at Aberdeen, and will shortly be illustrated in this journal. Its function is to draw on a fixed plate a magnified diagram of the ground's horizontal motion; the figures, which are generally of great complexity, are given by Mr. Sekiya for a number of recent Japanese earthquakes.

A short paper follows by Mr. E. Knipping, "On the Meteorology of Japan," gathered from observations made at twenty-three stations during the year 1883. It mentions that the annual variation of temperature for that year in Japan was more than double that of Britain, and that changes of 14° C. or 15° C. at one station in twenty-four hours are not unfrequent in the spring and autumn.

A paper by Father Faura, S.J., of Manila, describes the Cecchi seismograph—an instrument belonging so decidedly to the old school of seismology that, by allowing its description to appear without criticism, the Society at least shows its catholicity of spirit.

Dr. Dubois contributes some notes on the earthquakes of Ischia, and refers to the effects—or rather absence of effects—of the earthquakes in excavations there, in support of the fact that seismic shocks which do much damage on the surface may pass unperceived at a certain distance beneath.

The volume concludes with a catalogue of earthquakes registered in the meteorological observatory of Tokio by Palmieri's recording seismoscopes. The list for 1884 shows the respectable total of seventy distinct disturbances, and twenty-eight were registered in the first four months of 1885.

J. A. EWING

RECENT ADVANCES IN SANITARY SCIENCE

"HYGIENE," in the words of the late Professor Parkes, "is the art of preserving health; that is, of obtaining the most perfect action of body and mind during as long a period as is consistent with the laws of life. In other words, it aims at rendering growth more perfect, decay less rapid, life more vigorous, death more remote." The art of preserving health is correlative with the science of prevention of disease, since perfect health means the absence of disease and of tendencies to disease. Hygiene is thus the art of preserving health and the science of preventing disease; and in taking into account recent advances in sanitary science we must consider recent acquisitions in our knowledge of the origin, causes, and spread of disease, more especially of those diseases known as "preventable," as well as the methods of improving the natural conditions or social relations surrounding us, which are instrumental in preserving health and counteracting disease.

The etiological relations of all diseases are a subject of interest to the sanitarian, but those which have received the most attention of recent years, and in which the most striking advances of knowledge have either already been made, or are imminent in the near future, are perhaps Asiatic cholera, typhoid or enteric fever, diphtheria, and phthisis or tubercular disease of the lungs. The mode of origin and spread of Asiatic cholera has attracted great popular attention, both on account of its possible introduction into this country from infected districts of the Continent, and from the alleged discovery by Koch of a *Spirillum* or *comma-Bacillus* asserted to be the specific cause of this terrible disease. The Report of the Government Commission consisting of Drs. Klein and Heneage Gibbes, who visited India in 1884 with the object of undertaking researches into the etiology of Asiatic cholera, has lately appeared, and in this Report the conclusions arrived at by Koch from his own researches are very directly traversed. This Report, too, has received a very cordial support from a Committee consisting of many eminent physicians and physiologists, which was convened by the Secretary of State for India for the purpose of taking it into consideration. It must be apparent, however, to any one who makes an impartial study of the literature of the subject, that, if Koch's organism has not yet been proved to be the actual cause of the disease, it has been proved to differ from all other organisms asserted to be identical with it, from the fact that its growth in various nutrient media is characteristic, and serves to distinguish it from all other organisms. As far as our knowledge at present extends, difference in manner of

growth in nutrient media affords as just a basis for distinction between micro-organisms as difference in microscopical appearance or other morphological characteristics. Koch's comma-Bacillus is therefore diagnostic of the disease, and this fact has now placed in the hands of medical men the power of at once recognising a true case of Asiatic cholera, the isolation of the organism from others in the choleraic discharges and its cultivation in suitable media being alone needed. The results of Koch's researches, whether fully accepted or not, have not affected, nor are they likely to affect, the measures on which reliance alone can be placed for the prevention of outbreaks and spread of the disease. In the words of the Committee before alluded to, "Sanitary measures in their true sense, and sanitary measures alone, are the only trustworthy means to prevent outbreaks of the disease, and to restrain its spread and mitigate its severity when it is prevalent Experience in Europe and in the East has shown that sanitary cordons and quarantine restrictions (under whatsoever form) are not only useless as means for arresting the progress of cholera, but positively injurious."

The view that typhoid fever cannot arise *de novo*, but is always propagated by a specific contagion from a previous case of the disease, is steadily gaining ground, as the number of epidemics where the disease has been definitely traced to specifically polluted air or water increases. In many other cases, although the specific pollution has not been definitely proved, the probabilities in favour of such a view have been very great. No micro-organism has yet been found which can lay claim to be regarded as the specific contagion of the disease, but we are in possession of so many facts concerning the mode of origin and spread of this disease, that any discovery of that nature would probably not greatly affect the measures now taken for its prevention.

The etiology of diphtheria has lately received very careful study, but so far without the attainment of any results capable of exact formulation. It is not a disease invariably dependent on insanitary conditions, such as typhoid fever is, but that such conditions favour its spread and severity is more than probable. The far greater comparative frequency of diphtheria in rural districts than in large towns in this country is well known, and has been attributed to the presence in the air of the latter of the products of coal combustion. This view appears the more probable seeing that Continental cities, where wood and not coal is chiefly used as fuel, enjoy no such comparative immunity from the disease. Excessive moisture in the air of a house, whether arising from defective construction of the walls or roof, or from a water-logged soil, are conditions very often associated with diphtheria. The fact also that the disease is most prevalent in the damper seasons of the year, when vegetable matter is undergoing decay and fungus life is most active, favours the theory that the specific contagium of this disease is a mould or fungus, which flourishes most strongly in a damp and smokeless air. It is a remarkable fact that diphtheria is sometimes associated with scarlet fever in one epidemic, the two diseases appearing to be interchangeable; but this is a subject that requires further elucidation. The contagion of diphtheria is extremely persistent and long-lived, clinging with great pertinacity to infected articles, so that every article which is likely to have become contaminated requires very thorough disinfection, preferably by heat. There can be no doubt that school attendance is often a chief factor in the propagation of the disease amongst children.

Koch's discovery of the *Bacillus tuberculosis*, a micro-organism now proved to be the specific contagium of tubercular disease in men and animals, has placed tubercular phthisis in the category of contagious diseases. A peculiar disposition or tendency, whether hereditary or acquired, is no doubt wanted to enable the germ to take up its habitat in the human lung, but the fact that this idiosyncrasy can seldom be definitely recognised renders great caution necessary both on the part of members of a family in their association with a consumptive relation, and of hospital authorities in admitting into a general ward cases of tubercular disease, or of massing together into one institution patients in every stage of the disease. The Bacillus is constantly present in the sputum and probably in the breath of phthisical patients, and this points to the necessity of free ventilation of living and sleeping apartments, and disinfection of soiled articles of clothing and furniture. The external conditions which, of all others, cause a predisposition to consumption are, a damp subsoil, causing excess of moisture in the air, and the constant breathing of an atmosphere vitiated by human respiration. It has been asserted that tubercle can be propagated from animals to man by the consumption of diseased meat, or, in the case of the cow, from the milk of a tuberculous animal. Further proof is required before we can accept such an hypothesis, but there is nothing improbable in such a mode of conveyance of the disease, especially in the case of children with a tubercular predisposition.

Besides the diseases which we now know to have been propagated through the agency of milk—enteric fever, scarlet fever, diphtheria, &c, in which the introduction of the morbid matter is accidental, the milk serving only as a means for its conveyance and perhaps for its growth—there is a complaint fairly definite in character, which has been attributed to the consumption of the milk of cows suffering from foot-and-mouth disease. Here the morbid quality is inherent to the milk as taken from the cow, and is not due to an accidental introduction. The symptoms described in the epidemics recorded are fever, vesicular eruptions on the lips and in the throat and mouth, and enlargement of the glands of the neck. During the prevalence of foot-and-mouth disease, all milk taken by a household should be boiled before consumption. In view of the many dangers which threaten us through the agency of milk, it would perhaps be advisable, especially where children are the chief consumers, that this precaution should be always adopted; at least until the sanitary authorities in towns have the power of inspecting and controlling the farms and dairies in the country from which the chief part of the milk-supply is derived.

The possibility of the transmission of the contagion of small-pox for considerable distances, not exceeding one mile, through the air, has been warmly supported. There are many facts in favour of such a view, and its great probability will be seen from the following considerations. The contagion is almost undoubtedly a micro-organism of the class Bacteria, but as it has not yet been isolated and identified, we are unaware if it is capable of spore-formation or not. The spores of Bacteria can resist external agencies—heat, cold, drying, and antiseptics—to a much greater extent than the fully formed organisms, and it is probable that those diseases in which the contagion remains dormant for long periods are transmitted through spores capable of existing for long periods outside the body. But in small-pox it is not necessary to rely upon spore-formation to support theories of aërial transmission. The contagion as given off from the body of the patient is inclosed in minute epithelial scales and dry pus accumulations. Here, protected from the air and from external destructive agencies, it may be wafted as a minute dust through the air, to descend at considerable distances. That the radius of infection from a small-pox hospital as a centre does not exceed a mile may be due to the great dilution of the contagion as it is diffused through greater distances than a mile from its centre of origin, the hospital. The observations of Dr. Miquel, at the observatory of Montsouris near Paris, have shown the number and variety of solid particles which are carried in the air, and the immense distances which some of them, as pollen and spores, may be presumed to have travelled. An educated

public opinion will soon, if it does not already, regard small-pox hospitals as possible centres of infection, and will insist on their removal outside inhabited areas.

The compulsory notification of infectious diseases to sanitary authorities, either by the householder in whose house the case occurs, or by the medical attendant, or by both, has been adopted in numerous provincial towns during the last five years. This measure has done much to furnish the authorities with early information of the occurrence of infectious disease which would not otherwise have been obtained, and such information has doubtless enabled the sanitary officials to stamp out many an epidemic in the bud, which might otherwise have reached large dimensions. The more universal adoption of a measure of compulsory notification in our large towns is urgently needed.

In the domain of domestic sanitation the advances of recent years have been mostly limited to the practical applications of sound principles already acquired to the carrying out of works of construction, drainage, or water-supply of the dwelling. Houses built for the use of the well-to-do classes (not those of the speculative builder) in recent years will most generally be found to be planned and fitted on modern sanitary principles. Thorough ventilation of the drain and soil-pipe, disconnection of the waste-pipes of baths, sinks, and lavatories, and of the overflow-pipes of cisterns from the drainage system, are now understood to be necessaries of modern life. A break in the connection between the house-drain and the public sewer by means of a manhole chamber and water-seal or trap, though not considered necessary or desirable by all, is now very usually practised. We cannot doubt that the air of a public sewer is sometimes the means of disseminating disease, and any method which practically excludes such a source of danger from our houses is one to be encouraged. As knowledge extends, the simplest form of apparatus is found to be the best; many of the more complicated kinds of traps and contrivances for excluding sewer air are now discarded by builders and architects for those simpler forms which are equally effective.

In the matter of water-supply, the belief is steadily gaining ground that a water once polluted by sewage cannot be regarded as safe for drinking purposes. Safe it may be so long as filtration on the large scale is efficiently performed, but any failure to thoroughly filtrate and aërate the water in times of epidemic visitation might be attended with disastrous consequences, even supposing that filtration through sand and gravel is destructive of disease organisms or their spores. The introduction of a constant supply of water into towns, in the sense that cisterns and receptacles for storing water are no longer necessary, has been of great benefit—especially in the poorer parts of towns, where water stored on the premises is usually highly contaminated.

Of the scientific witnesses who were examined before the Royal Commission on Metropolitan Sewage Discharge, nearly all were in favour of the principle of separation of the rainfall from the sewage. "The rain to the river, the sewage to the soil." In view of the ultimate disposal of the sewage, the advantages of the "separate method" are very great, and would now probably lead to its adoption in any new scheme of sewerage for a town where the circumstances are favourable. From the public health point of view, it is also desirable to have impermeable pipe or brick sewers of small size, so that contamination of the soil by leakage into it of the contents of sewers may be avoided. In any such scheme of sewerage it must not be forgotten that not only are channels on the surfaces of the streets and roads required to convey away surface water, but pervious drains laid in the subsoil are absolutely necessary in the health interests of the town to keep the subsoil water at a permanently low level. For the disposal of the sewage, the value of a regular daily flow, and the elimination of the necessity in times of heavy rain of dealing with an enormous and uncontrollable volume of dilute sewage, must be obvious. The surface waters of towns are certainly not clean, but where the streets are efficiently scavenged they are free from taint of human excretal refuse, and fit for admission into the rivers which nature intended as drainage channels of the surrounding high lands.

The extreme importance of thoroughly ventilating sewers, is now very generally understood. Pipe sewers require as much ventilation as brick sewers, although the absence of deposit on the smooth internal surfaces of the pipes, and their consequent freedom from smell due to decomposition of deposited organic detritus, originally led to the belief that ventilating openings were not required in pipe systems of sewerage. It was not until Dr. Buchanan showed in the case of Croydon that the absence of proper ventilation in the pipe sewers of that town was in all probability instrumental in aiding the spread of enteric fever that the opinion of engineers on this matter underwent a change. Displacement of air in pipe sewers of small diameter is greatly more sudden than in brick sewers of larger diameter, and it is plain, says Dr. Buchanan, that "means of such ventilation are wanted more numerously in proportion as the displacements of air may be local and sudden." Openings into sewers from the street level are still regarded as the best practicable means for the admission of fresh air, and the exit of sewer air. Charcoal trays, Archimedean screws, and other contrivances for purifying the issuing air, or hastening its exit, are now generally abandoned as useless and inconvenient.

The purification and utilisation of the sewage of towns is a subject of much importance both in its public health and commercial aspects. The idea, so long entertained, that town sewage could by various methods be made to yield a manure which would give rise by its sale to an enormous profit is now exploded. The highest degree of purification, we now know, can only be attained on land naturally suitable from its porosity and other properties, and artificially prepared by extensive under-drainage. The agents which purify sewage in its passage through soil, by converting the nitrogenised organic matters into inorganic salts—nitrates and nitrites of the alkaline and earthy bases, and ammonia—have been discovered to be Bacterial micro-organisms, resident chiefly in the superficial 18 inches of soil, and far more abundant in some soils than in others. Sewage farming has been ascertained to be profitable, under suitable conditions. The sewage must flow from the town to the farm by gravitation—the cost of pumping will neutralise profits from the sale of farm produce; a part of the farm must be laid out as a filter bed, so that the sewage, when not required on the cultivated land or when so dilute from the presence of storm waters as to be inapplicable, may be purified on a small very porous area by the process of intermittent downward filtration. Very few growing crops are benefited by the application of sewage, except the various kinds of grasses, and of these such enormous quantities can be produced that, unless converted into "silage," or utilised on the farm in the production of stock and dairy produce, they may be expected to result in a loss, from the absence of any demand for such large quantities at all periods of the year.

In this country, the sewage farm at Birmingham is probably the best example of what has been done to solve a most difficult problem by the application of sewage to land. Here, the sewage is first freed from its suspended matters by a process of precipitation, a proceeding necessary not only to prevent warping of the land with offensive solid matters, but also to withdraw the metallic salts and acids incidental to the sewage of a manufacturing town, which would be injurious to vegetation. Even this magnificent example of dealing satisfactorily with the most difficult municipal problem of modern times is eclipsed

by the city of Berlin on the Continent. The sewage farms at Berlin have successfully dealt with the sewage of 387,500 people—nearly twice the population of Birmingham—whilst London is still allowing to run to waste an enormous amount of valuable material, at the same time polluting a river—the highway of its commerce to an extent never previously dreamt of.

Processes of precipitating sewage by chemicals are now known to exert only a partially purifying influence. The best process yet discovered can do little more than free the sewage from its suspended matters, allowing all the dissolved constituents of sewage—by far the most valuable portion agriculturally and chemically—to pass away in the effluent. Lime dissolved as lime water, sulphate of alumina, and perhaps proto-sulphate of iron, taken together and added to the sewage in the proportion of not more than 10 to 15 grains to the gallon, are the best, most economical, and most effective precipitants. Other more valuable substances, added to the sewage with the view of increasing the value of the precipitated sludge or manure, are in large proportion lost in the effluent water, and as they do not assist precipitation might just as well be added to the sludge afterwards, if fortification is required. Half-a-crown and no more is the value per ton of the precipitated solids of sewage. This value will generally pay for the cost of their carriage a mile or so in agricultural districts, but no further.

A great improvement in dealing with the semi-liquid sewage sludge has been lately effected. The sludge containing over 90 per cent. of water was formerly allowed to dry in the air or in a drying chamber, and a most intolerable nuisance resulted. It is now possible by means of hydraulic filter-presses to convert the semi-liquid sludge into solid cakes containing 40 to 50 per cent. of water, and in this form it is innocuous to the senses, and can be readily conveyed away by cartage.

The knowledge already acquired demands that now, and in the future, the sewage of towns should, whenever possible, be utilised on land in the production of crops or dairy produce; failing this, the sewage should be freed from its solids by precipitation, and subsequently purified on land laid out as filter-beds, efficient purification, and not the production of crops, being alone aimed at. If application to land is impossible, then precipitating processes alone must be relied on, and where the sewage can be turned into the sea, and effectually got rid of without nuisance, there it may be allowable to waste valuable matter which cannot be utilised except at a cost destructive of all profits from its utilisation.

SALE OF THE JARDINE ORNITHOLOGICAL COLLECTION

THE dispersal of an ornithological collection so large, and of such historic interest, as that formed by the late Sir William Jardine, F.R.S., is an event deserving of notice. The collection was begun more than sixty years since, and was the occupation of half a century's diligent care. From its contents were described, and often figured, a majority of the species treated of in the late baronet's many works, ranging from the "Illustrations of Ornithology," commenced in 1825, to papers in journals of comparatively recent date, and it included a greater number of "type-specimens" than any other that has ever been brought to the hammer.

On Sir William's death in November 1874, it was understood that the collection would be speedily sold, and a strong hope was entertained by ornithologists that it should pass, *as a whole*, into one or other of the great museums of this country. However, this was not to be. The comparatively small "British" portion was, after a time, purchased by the Museum of Science and Art in Edinburgh, a very fitting destination for it; but the rest, consisting of between 8000 and 9000 specimens, remained in the hands of Sir William's heir. At last that gentleman determined to dispose of it by auction, and for that purpose selected Messrs. Puttick and Simpson, the well-known firm of Leicester Square, by whom it was accordingly sold on Thursday, June 17 last. However, the attendance at the sale was but small, and except in a very few instances, the prices obtained were below the average often reached at sales of collections in every way inferior in interest, while not one of the lots attained a price that may be called high. There was a certain competition among a few experts, but even this was not carried to any excess, and as a rule the prizes of the collection were knocked down for very small sums. It is a satisfaction to read, however, that most of the "type specimens" were secured for the British Museum or for that of the University of Cambridge; but few, it is believed, falling into the hands of dealers, and hardly any, as was to be greatly feared, into those of the "plume-trade." The low prices realised were due, no doubt, to the fact that notice of the sale had reached few amateur collectors in time, and added to this was the fact, obvious on inspection, that the sale catalogue supplied very little of the information which collectors require. It was the general impression in the auction-room at the time, and has since been confirmed by the opinion of practical ornithologists, that had the catalogue set forth the special quality of the specimens, and the sale been made known more widely, a very different result would have followed, and something like the competition which attended the great sale of Mr. Bullock's museum in 1819 might have been attained, for collectors are as keen now as ever, and such a chance as this is not likely to occur again to the present generation. The long period, too, which has elapsed since Sir William Jardine's death (recorded in NATURE, vol. xi. p. 74) possibly helped also to divest the sale of his collection from a good deal of the interest which it would have inspired had its dispersal taken place soon after his decease, for memories are short in these days. The agent of the British Museum has to be congratulated for his promptness in recognising and securing at a nominal price for that institution one "type-specimen" (that of Bulwer's petrel), which, not being mentioned in the catalogue nor occurring in its expected place among the other specimens of its family, had escaped the notice of all the other ornithologists who had viewed the collection.

NOTES

AMONG the Colonials on whom honours have been conferred are Dr. Julius Von Haast, F.R.S., who has been made K.C.M.G., and Dr. A. R. C. Selwyn, who has been made C.M.G.; Dr. G. Watt, of the Indian Department of Revenue and Agriculture has been made a C.I.E.

PROF. PAUL WAGNER, on behalf of the Comité Salitero, sends us the following statement as to the result of the nitrate of soda competition. Carrying out the scheme of prizes offered by the Committee of the Saltpetre Producers' Association (Comité Salitero at Iquique, Chili) for the best popular essay treating of the importance of nitrate of soda as a manure, and the best mode of its application, the judges—Prof. L. Grandeau, Nancy (France); Prof. Adolf. Mayer, Wageningen (Holland); Prof. A. Petermann, Gembloux (Belgium); Prof. G. Thoms, Riga (Russia); Prof. Paul Wagner, Darmstadt (Germany); Mr. R. Warington, Rothamsted (England)—have examined the essays sent in, namely, thirteen German, thirteen English, and four French, and have made the following awards:—(1) To the essay with the motto, "Grau, theurer Freund, is alle Theorie," a partial prize of 350*l*. (7000 marks); (2) to the essay with the motto, "Pour pratiquer l'agriculture . . . . " a partial prize of 150*l*. (3000 marks). On opening the accompanying envelopes, the author of the first essay was found to be Dr. A. Stutzer.

Principal of the Agricultural Experimental Station at Bonn; and the author of the second essay, M. A. Damseaux, Professor in the Agricultural Academy at Gembloux. It should be remembered that essays competing for the second part of the prize offered—namely, 500*l.* for the best essay treating of the same subject, on the basis of *new, personal, experimental investigations*—must be sent to one of the above-named judges, on or before January 1, 1887.

THE Local Committee for the Birmingham meeting of the British Association have their arrangements well forward. A considerable contingent of Canadian and other colonial men of science will no doubt be present, and every effort will be made to extend a hospitable welcome to them and to all the members of the Association who may be able to visit Birmingham. The Great Western, the London and North-Western, and the Midland Railway Companies offer exceptional facilities to intending visitors. The Council of the Birmingham and Midland Institute have placed their spacious lecture theatre, with its convenient suite of rooms attached, at the disposal of the Local Committee as a reception-room, officers' and ladies' rooms, &c. The meetings of the Sections will be held in the Council House, the Mason Science College, the Medical Institute, the Birmingham Municipal School of Art, and in the offices of the Board of Guardians—buildings which closely adjoin each other; and the use of rooms in the Council House has also been granted by the Mayor for other purposes. The Town Hall will be utilised for the evening meetings. Various clubs and scientific and literary institutions will be thrown open to members and associates by the courteous invitation of the governing bodies, and the Committee of the Birmingham Botanical and Horticultural Society will open their Gardens during the week of the meeting to members and associates. The Committee are also preparing an extensive exhibition of the products of local industries and of local manufacturing processes, which will be held in Bingley Hall. A collection of the flora and fauna, together with the rocks and fossils of the district, will be shown in connection with this exhibition. The Committee are arranging a series of excursions to various localities of great beauty and interest, and many kind offers of hospitality have been received in connection with the projected excursions. The Committee are engaged in the preparation of a guide-book of the town, which will include an account of its history and antiquities, trade and manufactures, a description of its modern government, papers on the geology and physiography (accompanied by a geological map), and the zoology and botany of the district.

SOME of the friends of the late Dr. Walter Flight are anxious to collect a fund to be invested for the benefit of his widow and children, who have been left with extremely inadequate provision. A Committee has been formed with the Rev. Prof. Bonney, F.R.S., as chairman, to carry out this object. The honorary treasurer is Mr. L. Fletcher, Natural History Museum, Cromwell Road, S.W., and the honorary secretaries T. W. Carmalt Jones, M.D., 6, Westbourne Street, Hyde Park, W., and John M. Thomson, King's College, Strand, W.C. Contributions may be paid to the account of the "Flight Memorial Fund" with Messrs. Robarts, Lubbock, and Co., to the honorary treasurer, or either of the honorary secretaries. We need not say a word to impress upon our readers how deserving is such a case as this.

A MOVEMENT is on foot for obtaining subscriptions to purchase an annuity for Mr. J. B. Dancer, who has done so much for the improvement of photography. But photography is only one of the many arts and sciences indebted to him. There is the stereoscopic camera with twin lenses, which he was the first to make. He invented microscopic photographs, which so much delighted and astonished us twenty-five or thirty years ago. He also introduced photography to the magic lantern, being the first to show a photographic transparency on a screen. The lantern itself is also indebted to him, not only in its optical parts and in its construction generally, but also particularly in the application of the oxy-hydrogen light, and for a dissolving gas tap, which saves half the gases and produces the best dissolving effect. Then there should be mentioned, as of much greater importance than the above, the automatic "contact-breaker," used probably by the million at this moment, in every induction coil in the world. Prior to Mr. Dancer's invention, contact used to be made and unmade by hand, in a vessel containing mercury. The first helical coil with the vibrating interrupter was constructed by Mr. Dancer, and was exhibited long after by him at one of the *soirées* of the British Association, when the meeting was held in Manchester. When Mr. Dancer established himself as an optician in Manchester, his presence soon made itself felt amongst the few microscopists then living in the district. Good microscopes were then costly, and worthless ones very common. Mr. Dancer successively brought out several forms of instruments, as excellent in their mechanical and optical arrangements as they were moderate in price. It is sad to have to say that, notwithstanding Mr. Dancer's talents and achievements, he is now living in very straitened circumstances, is morever afflicted with almost total blindness, and therefore unable to follow the optical business to which his life has been devoted. It is not an unusual thing for a man of great mechanical ingenuity and skill to be an indifferent man of the world, and so it has been with him; as a business man he has been a failure. He has made improvement after improvement, invention after invention, any one of which might in "pushing" hands have made a fortune; but, more interested in science than in money-making, he has allowed the golden chances to become public property, and has thus remained poor himself, while the world has reaped the advantage of his labours. Mr. Dancer is now in his seventy-fourth year, and, it is to be hoped that in his hour of darkness the world will pay back to him something for that which it has freely received at his hands. A Committee has been formed for the purpose of receiving subscriptions, and we commend the movement strongly to the support of our readers. The Committee are: J. P. Joule, LL.D., F.R.S., Sale; Prof. W. C. Williamson, LL.D., F.R.S., Owens College; Prof. Balfour Stewart, LL.D., F.R.S., Owens College; John Dale, F.C.S., Cornbrook, Manchester; Leo H. Grindon, Manchester; S. Platt, J.P., Oldham; Charles Bailey, Hon. Treasurer Manchester Literary and Philosophical Society; James Birchall, Hon. Sec. Liverpool Literary and Philosophical Society; Abel Heywood, jun., Higher Broughton (Hon. Sec. *pro tem.*).

DR. ULLMANN, of Vienna University, who spent several weeks with Dr. Pasteur in Paris, and brought back some of the virus with him, began on Monday, in the presence of several eminent professors, to inoculate against hydrophobia. He had for patients thirteen men bitten by rabid dogs and one woman bitten by a rabid pig.

WE regret to announce the death, on the 23rd ult., at his residence, Glenoir, Galway, of William King, D.Sc., Emeritus Professor of Geology, Mineralogy, and Natural History in the Queen's College, Galway, in his seventy-eighth year. Upon the foundation of the Queen's Colleges in Ireland, in 1849, Dr. King was selected to fill the Chair of Geology in the Galway College, a post that he occupied, and of which he fulfilled the duties most assiduously and laboriously, until 1883. In that year, owing to a severe attack of paralysis, Dr. King was most reluctantly obliged to relinquish his professorial duties. In 1882 the additional performance of the business of the Natural History Chair devolved upon him: the double task proved too onerous. Subsequent to his resignation, the Corporate Body of the College presented Dr. King with an address, as a testimony

of their esteem for his devoted services, of which latter the Geological Museum in the College is a lasting record. Numerous volumes and also pamphlets upon various branches of geology bear witness to his attainments and indefatigable zeal.

FROM the report just issued by the Swedish Academy of Sciences we gather some interesting particulars of the scientific work prosecuted under the auspices of this Institution last year. On the recommendation of the Academy the following sums were granted by the Government towards scientific research, &c. :—A sum of 150*l*. to the Academy's Zoological Station in the province of Bohus; 200*l*. to Prof. H. Gyldén for the development of his theory respecting the movements of the larger planets; 250*l*. towards the publication of the *Acta Mathematica;* 300*l*. towards the purchase of a zoological and ethnographical collection of objects brought by Dr. C. Bovallius from the West Indies and Central America; 60*l*. towards Prof. Liljeborg's work, "Scandinavian Fishes"; and two sums of 50*l*. each towards Herr Westerlund's work, "Fauna der in der palàarctischen Region lebende Binnenconchylien," and Dr. Lindeberg's exsiccate work on the Rubi of Scandinavia. In addition to these sums, various smaller amounts were granted by the Academy to a number of gentlemen towards scientific researches, as, for instance, for the study of certain algæ on the coast of Bohus, for the study of the Scanian moss flora, for the study of the anatomy and histology of the marine Annelidæ in the same province, and that of the Gasteropoda, &c. Of other scientific work continued last year may be mentioned the work on the great publication recording the scientific of the expedition to Spitzbergen, 1882–83, of which the researches on the aurora borealis and the electricity of the air are now in the press, and the rest, on other branches of science, will shortly follow; and further, the arrangements of the valuable collection for the State Museum of ethnographical objects from all parts of the world—some 6000 in number—made by Dr. Stolpe during the voyage of the corvette *Vanadis* round the world. The Academy also purchased a large estate near Stockholm with the funds bequeathed by Prof. Bergius for the establishment of a horticultural garden, similar to that of Kew, to be under the supervision of the Academy. An important change has been decided on with reference to the publishing of the Academy's *Journal*, viz. to divide it into two parts—Proceedings and Appendix—the former to be issued monthly, containing reports of meetings and short papers and the latter to be issued at intervals, containing longer and more scientific papers; and these will be divided into four sections, each embracing a certain branch of science, which will enable a specialist to find at once the paper desired, and not necessitate the purchase of the whole yearly series.

AN Australasian Meteorological Society has been formed at Adelaide, South Australia.

ON Edison's system of telegraphing with trains in motion, the *Scientific American* (February 20, 1886) says:—The receiving apparatus at both the car end and the fixed end of the line is a telephon·. The sending apparatus is also similar at both ends, and consists of an interrupter or vibrating tongue driven by an independent battery, and making 500 vibrations per minute; this vibrator is in circuit with the line battery, an ordinary Morse key, and the primary of an induction coil. The secondary of the induction coil on the car is in connection with the tin covering the entire roof of one or more cars; the secondary coil at the fixed station is in connection either with condensers or with other induction coils, which in turn are in connection with the ordinary line wires by the side of the track. Suppose a message to be sent from the fixed station to the car. The vibrator is always working, but till the Morse key is put down no current passes. The message is sent by the ordinary Morse signal, only instead of a continuous current being sent to line each time, it is an alternating one; this induces a current in the secondary coil, and through it the condensers, for example, are charged alternately. The charge of the condensers is propagated through the line wires with which they are in connection, and influences the tin roof of the car, and ultimately the telephone by which the signals are read.

MR. BLANFORD, Meteorological Reporter to the Government of India, has issued a memorandum on the Himalayan snowfall in the past season. A few years ago, it will be remembered, Mr. Blanford propounded a theory of a connection between this snowfall and the monsoon, to the effect that the later and heavier the snowfall in winter and spring the later and feebler would be the following monsoon. The forecasts based on this theory were fairly accurate last year, and accordingly his forecast this year was looked forward to with anxiety on account of the great value of early and copious rain to Indian agriculture. This year Mr. Blanford arrives at the conclusion that, although a considerable amount of snow fell in the North-Western Himalayas and the hills of Eastern Afghanistan, during the winter and spring, especially in January and February, there has been on the whole less than in the previous year. The snow range, as seen from Simla, is less thickly covered than it was in 1885, and the snow is at a higher level. The winds have been less northerly than usual on the west coast, and more decidedly southerly and easterly in the Punjaub. Hence he thinks that there will be no retardation of the monsoon on the Bombay side; and the barometric levels are favourable to an advance of the easterly branch of the monsoon, so that no apprehension need be felt about the rains in Upper India.

AT the meeting of the Royal Society of Tasmania on April 13, the Curator of the Museum stated that during the past month Mr. Vimpany had captured a black snake (*Hoplocephalus curtus*) at Longley, measuring about 4 feet 3 inches in length. On opening it the unprecedented number of 109 young ones were found in her. The specimens now before the meeting are the largest ones, the measurement being from $8\frac{1}{2}$ inches to $\frac{3}{4}$ of an inch in length. Mr. Morton stated that the greatest number he had known previously to be taken from a similar snake was 32, but he had been informed by a resident of Tasmania that over 70 had been taken from a similar species.

IN the *Stonyhurst Magazine* for May 1886, is a list of the flora of the Stonyhurst district. It contains a list of all plants of whose occurrence within a radius of ten miles from Stonyhurst satisfactory record can be found.

FROM a communication by M. Nikolsky to the St. Petersburg Society of Naturalists (vol. xvi. 2), it appears that the drying up of Lake Balkhash is going on at a very rapid rate, and so far as the observations of the inhabitants may be relied upon, its level is lowered by no less than two feet every ten years. The maps of 1852 show that a very great reduction of the surface of the lake has taken place during the last thirty years. As to the fauna of Lake Balkhash M. Nikolsky makes the following interesting remarks. It does not include a single species of those fishes which are characteristic of the Aral-Caspian ichthyological region. On the other hand, there is a very great resemblance between the fishes of Lake Balkhash and the lakes on the high plateau of Central Asia, for instance, of Lob-nor. Three species are common to the Ili River and the Tarim, tributary of Lob-nor. M. Nikolsky concludes from the ichthyological data that there is no ground to admit of any direct connection between Lake Balkhash and Lake Aral. If there ever was a sea which covered the Siberian lowlands as well as the depressions of Lake Balkhash and the Aral-Caspian, the Balkhash was

separated from the latter at a period when the connection between the Aral-Caspian depression and the Arctic Ocean still existed. There was certainly, in recent geological time, a connection between the rivers of the Balkhash basin and those of the Lob-nor basin, which connection probably followed the Kunges, the Yulduz, and the Tarim Rivers.

THE total area of the Crown forests of Sweden at the beginning of 1885 was 5,785.535 hectares, being a seventh part of the total forest area of the country. The revenue from the same was a little less in 1885 than in 1884, but this is believed to be only incidental, it having risen from 750,000*l.* in 1880 to 890,000*l.* in 1882, and 1,120,000*l.* in 1884.

WE have received part 2, vol. iv. of the *Transactions* of the Norfolk and Norwich Naturalists' Society, containing the papers selected for publication and the address read by the President, Major Feilden, F.G.S., at the seventeenth annual meeting of the Society. From the report it appears that the Society now numbers 260 members, and is both numerically and financially in a very satisfactory condition. For his address Major Feilden chose the fascinating problem of the origin of life, which he strove to show must have had its advent at the poles of the earth, a subject which his study of the fossil and recent fauna of the polar regions as naturalist to the Arctic Expedition of 1875-76 gave him special opportunities of studying. The conclusions to which Major Feilden arrives are that through the secular cooling of our planet the poles became first fitted for the reception of life; that in palæozoic times the North Pole possessed a climate as warm, at least, as that now enjoyed at the equator; that the temperature at the North Pole during the Miocene period, though gradually cooling, supported a flora which spread southwards; and that in all probability animal life likewise originated at the poles, and spread towards the equator. Amongst the published papers, one by Mr. Clement Reid, F.G.S., on the "Flora of the Cromer Forest Bed," is of especial interest. Mr. Reid enumerates sixty species of plants, which he has obtained by the careful washing of clays from various localities near Cromer, and calls attention to the curious fact that all these, with the exception of *Trapa natans*, three firs, and *Isoetes lacustris*, are still indigenous to the county of Norfolk, and two-thirds of them are aquatic or marsh plants, identical in species with those found at the present day in almost all the Norfolk morasses. Mr. Edward Bidwell contributes an account of a visit to the Isles of Scilly in the nesting season of 1885; the Rev. H. A. Macpherson a paper on the habits and plumage of the Manx shearwater; Mr. G. Smith some notes on the habits of the Fulmar petrel; meteorological notes by Mr. A. W. Preston; notes on the herring fishery of 1885, by Mr. Southwell; a second paper, by Mr. Reid, on Norfolk amber; and a list of the birds of Norfolk, with remarks, by Messrs. Godney and Southwell; also a valuable paper on the gradual assumption of the adult plumage in the honey buzzard, by Mr. J. H. Godney.

WE have received a "Liste Alphabétique" of the Correspondence of Christian Huygens, which the Dutch Society of Sciences proposes to publish. The list may be obtained from Enschedé and Son, Haarlem.

DR. G. F. MARTINEAU, of Yorke House, Stourport, writes with reference to the article "On the Origin of our Potato," in NATURE of May 6 last, p. 7, that in turning over, the other day, the leaves of the sumptuous "Hortus Eystertensis" of Basil Besler, printed in Nuremberg in 1613, he found an excellent plate of the plant (of which he sends a tracing), with a clear and full description. Certainly it is quite worth while to draw attention to Besler's figure and text, but it tells one nothing new. There are good figures in Gerarde, 1597, and Clusius, 1601, Besler's being 1613. "The potato," another correspondent writes, "is not *wild* in Virginia; it must have been carried there from Peru and Chili. The only wild United States potatoes are high up in the Rocky Mountains. A. De Candolle's idea is that the potato was first brought to Europe, not by the English, but by the Spaniards."

THE additions to the Zoological Society's Gardens during the past week include a Chimpanzee (*Anthropopithecus troglodytes* ♀) from West Africa, presented by Capt. Reginald E. Firminger; a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mr. G. Ballentyne; a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mrs. S. M. Grove-Grady; a Banded Ichneumon (*Herpestes fasciatu*) from West Africa, presented by Mr. G. F. Stimpson; two Egyptian Geese (*Chenalopex ægyptiaca*) from Africa, presented by Col. Harris Burland; a Larger Hill-Mynah (*Gracula intermedia*) from India, presented by Miss Maud Bendall; a Martinique Gallinule (*Ionornis martinicus*) from South America, presented by Mr. W. J. Rae; Aldrovandi's Skinks (*Plestiodon auratus*) from North-West Africa, presented by the Hon. Walter de Rothschild; a Geometric Tortoise (*Testudo geometrica*), a Semiserrated Tortoise (*Testudo semiserrata*), an Angulated Tortoise (*Chersina angulata*), two Dwarf Chameleons (*Chamæleon pumilus*), two Keeled Euprepes (*Euprepes carinatus*), a Spotted Slowworm (*Acontias meleagris*), a Bipes (*Scelotes bipes*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Sand Lizard (*Lacerta agilis*), European, presented by Master Stanley S. Flower; two Ruffs (*Machetes pugnax*), a Common Viper (*Vipera berus*), British, deposited; a Silver-backed Fox (*Canis chama*) from South Africa, twelve Black-tailed Godwits (*Limosa ægocephala*), European, purchased; a Thar (*Capra jemlaica*), a Pigmy Hog (*Porcula salvania*), twelve Mandarin Ducks (*Æx galericulata*), a Chilian Pintail (*Dafila spinicauda*), a Red-crested Pochard (*Fuligula rufina*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

BLACK TRANSIT OF JUPITER'S FOURTH SATELLITE.—The fourth satellite of Jupiter was observed in black transit by Mr. E. E. Barnard of Nashville, Tenn., U.S.A., on May 8 with a 6-inch refractor. It was first noticed as a black spot at 9h. 20m. local mean time. Some little time previous to this it had been looked for on the disk but could not be seen either as a white or dark spot. The satellite was followed until 9h. 43m., and was then very black and rather small and round when best seen.

COMETS BROOKS I. and III.—The following ephemeris for Comet Brooks I. is by Dr. A. Berberich (*Astron. Nachr.*, No. 2731):—

For Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log *r*	Log Δ	Brightness
July 3	8 11 33	8 43·6 S.	9·8945	0·1128	2·0
7	8 37 32	9 49·2	9·9405	0·1400	1·4
11	9 0 24	10 37·4	9·9811	0·1680	1·0
15	9 20 32	11 13·6	0·0172	0·1957	0·8
19	9 38 22	11 41·5	0·0498	0·2227	0·6
23	9 54 15	12 3·9	0·0794	0·2487	0·5
27	10 8 30	12 22·7	0·1064	0·2734	0·4
31	10 21 25	12 39·1 S.	0·1314	0·2969	0·3

The brightness on April 29 is taken as unity.

Comet Brooks III. is now very faint, and will be soon altogether out of sight. Dr. S. Oppenheim gives (*Astron. Nachr.*, No. 2735) the following places for Berlin midnight on July 4 and 8:—

	R.A. h. m. s.	Decl. ° ′
July 4	13 18 40	16 42·6 S.
8	13 29 17	18 48·3 S.

NOVA ORIONIS.—The new star discovered by Mr. J. E. Gore near χ_1 Orionis appears for some unexplained reason to be a difficult object for photometric observations, the estimates of its magnitude made by various observers differing remarkably. Thus Dr. G. Müller found it a little brighter than the 6th magnitude

in the last days of December 1885—December 19, 5·86 m.; December 20, 5·76 m.; December 30, 6·00. Profs. Glasenapp and Pritchard both found it considerably fainter than the 6th at this time, the former giving it as 6·7 m. on December 30, the latter 6·42 m. on December 28. Profs. Müller and Pritchard give closely accordant results for the middle of January 1886, the magnitude being about 6·8 m., whilst Prof. Glasenapp and Mr. Gore found it about 7½ m. at the same time. Profs. Pritchard and Müller disagree a little later on, and differ by a full magnitude at the end of February and beginning of March, the former regarding the star as about the 7th magnitude, the latter about the 8th, whilst MM. Glasenapp and Gore consider it as nearly the 9th. There is a better agreement amongst three of the observers as to the range of magnitude through which the star has passed; Dr. Müller and Mr. Gore, agreeing in giving 2·4 m. for the change from about December 20 to March 8, and Prof. Glasenapp finding nearly the same value, but Prof. Pritchard, on the other hand, only finds a change in the same period of about seven-tenths of a magnitude.

10 SAGITTÆ.—Mr. Espin, in *Circular* No. 5 of the Liverpool Astronomical Society, gives the interval from maximum to minimum for this star as 4·4d.; maxima for July, 1·6d., 9·9d., 18·3d., 26·6d.; minima, 6·1d., 14·4d., 22·7d., 31·0d.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *JULY* 4–10

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 4

Sun rises, 3h. 52m.; souths, 12h. 4m. 6·4s.; sets, 20h. 16m.; decl. on meridian, 22° 53′ N.: Sidereal Time at Sunset, 15h. 7m.

Moon (three days after New) rises, 7h. 7m.; souths, 14h. 36m.; sets, 21h. 53m.; decl. on meridian, 13° 19′ N.

M signifies maximum; *m* minimum.

NATIONAL SMOKE ABATEMENT INSTITUTION[1]

DURING the year the interest in the subject of smoke prevention and in improved apparatus for the consumption of fuel has been steadily increasing, and the gradual extension of knowledge on the subject has led the general public to take a much more intelligent and active interest in the question of smoke abatement, which was at first considered by the great majority of the community to be almost a sentimental evil rather than a matter entering into the calculation and care of ordinary life. The Council regret, however, to note that the Annual Report of the Commissioner of Police, issued in August last, is strangely deficient with regard to information as to the operation of the Metropolitan Smoke Abatement Acts, which are administered by the police; and the Council thought it their duty to write to the *Times* and other daily papers, calling attention to this want of information in the Report, and also to the very anomalous character of the fines inflicted in the case of convictions; they also laid the matter before the Home Secretary, calling special attention to the following facts—

(1) That in numerous cases of nuisance which are reported by the police no proceedings are taken.

(2) That when proceedings are instituted, and convictions obtained, the penalties inflicted by the magistrates do not comply with the Acts of 1853-56, the average fine being below the legal minimum.

(3) That no proceedings whatever appear to be taken to enforce the abatement of smoke from steamers, &c., on the River Thames, although an enormous quantity of smoke is evolved by them, causing a very serious nuisance, not only in the waterside districts, but by polluting the general atmosphere of the metropolis.

(4) That such great development has taken place during the last few years in the methods of preventing smoke from the works falling under the provisions of the statutes, that they may be more rigidly enforced without hardship.

(5) That the area within which the Smoke Abatement Acts apply no longer corresponds with the area within which smoke is produced.

The Council were supported in thus calling the attention of the Home Secretary to the matter, by the fact that the Annual Report of the Commissioner of Police for the preceding year (1883) remarks strongly on the inadequacy of the fines, and states that, "The fact of recent changes in heating systems having brought about some very considerable commercial advantages of various kinds, has operated in a marked degree in mitigating hostility to the enforcement of the Acts."

The Council have also, through the medium of the Press, called attention to the fact that the London School Board are neglecting a public duty and losing a valuable opportunity of instructing the public, by having the large buildings recently erected for schools fitted up with heating apparatus without due regard to their smoke-consuming capabilites.

They have also endeavoured to influence public opinion by bringing under notice pledges which appear to have been given by some Parliamentary candidates, that they would endeavour to exempt bakers from the operation of the Smoke Abatement Acts, this pledge having been obtained by certain bakers who wished to maintain the use of a particular class of furnaces which ordinarily produce a large amount of smoke. It is scarcely necessary to point out that the exemption of bakers from the operation of the Smoke Nuisance Acts would be prejudicial to the public interest, as it is a fact that smoke can be and is in some bakeries entirely prevented, not only to the advantage of the public, but also to that of the men who work in the bakeries. The Parliamentary candidates themselves were also communicated with upon the subject.

The unreasonableness of the suggestion that bakers should be exempt from the provisions of the Smoke Acts is the more noticeable from the fact that the Commissioner of Police, in his Annual Report for 1883, alluding to the general improvement of heating methods, says: "The most important changes perhaps have been made in the case of bakers' and confectioners' oven furnaces, which have hitherto caused, and still continue to cause, the greatest number of offences charged under the Smoke Acts. Some of them are now adapted by a simple alteration, which can be made without stoppage of the daily trade, to the use of gaseous fuel (ordinary coal gas mixed with atmospheric air), instead of coal; while other ovens are heated by coke applied either directly to the purpose, or by steam, which is generated in pipes heated by means of coke-fired furnaces."

It may be added that the Council have had before them an offer from a good firm of oven builders, stating that they are prepared to fit up fifty bakers' ovens at half price, to prove the practical working of one system rendering such ovens entirely smokeless.

In various trades, notably baking confectionery, tile and porcelain burning, glass staining, japanning, &c., considerable advantages, in addition to the prevention of smoke, have been found to result from the use of coal gas instead of solid fuel for

[1] Report of Council of the National Smoke Abatement Institution, submitted at the ordinary general meeting, December 18, 1885.

furnaces and engines, but to obtain the same result the cost of gas is greater than that of coal. Although the directors of the gas companies of the Metropolis are apparently not unwilling to advance the cause of smoke abatement, and thereby of public sanitation, by making a reduction in the price of gas used for trade purposes, they are prevented doing so by their Acts of Parliament. The Council are keeping the matter in view, and watching a favourable opportunity to urge the Government to grant the necessary powers.

Correspondence has been carried on on the subject of the gas stoves at the Bank of England, insisting on the necessity of flues being provided to carry off the products of combustion from all gas stoves used for warming purposes, and letters have been received thanking the Institution on behalf of the clerks for calling the attention of the Bank authorities to the matter. Voluminous correspondence has also been carried on with makers and inventors of stoves and smoke-prevention appliances, and of patent fuels, and with others, giving information and suggestions on points connected with the subject too various to be set out.

During the year several tests have been carried out by the Institution, and they have now under consideration the preparation of another volume of detailed reports of tests. The volume would include tests of various forms of furnaces, steam and other boilers, blow-pipe furnaces, smoke-preventing appliances, ventilating fans, non-conducting compositions, mechanical stokers, condensers, gas cooking and heating stoves, and various heating and cooking appliances using gas and coal as fuel.

The Council had at one time intended to exhibit at the Parkes Museum typical forms of heating and smoke-abatement appliances, but for various reasons they considered it undesirable to carry out the scheme, and they propose instead to promote periodical exhibitions of special heating apparatus, or new methods of heating and smoke prevention, as opportunity may offer.

In connection with this branch of the subject, reference may be made to the exhibition of the Sanitary Institute held at Leicester in September, at which various stoves and smoke-preventing appliances were exhibited. Exhibitions of gas stoves for heating and cooking purposes have also been held in many of the chief provincial towns during the year.

A memorial, praying for a grant from the surplus funds of the International Health Exhibition, signed by the Duke of Westminster and other influential persons, was unavailing, although the object of this Institution so directly affects public health, the improvement of which was the avowed aim of the Health Exhibition. This is much to be regretted, as the lack of funds not only militated against the general operations of the Institution, but it prevented the Council establishing a testing department, which is a necessary adjunct to the Institution for the advancement of its objects.

During the year a lecture given in the Parkes Museum by Mr. T. Fletcher, of Warrington, on Smoke Abatement, and a pamphlet containing three prize essays on the same subject, have been printed by the Institution and circulated. A paper by Mr. W. R. E. Coles, on the Hygienic, Moral, and Economic Aspects of the Smoke Question, read at the Leicester Congress of the Sanitary Institute, is now being prepared for circulation.

By order, E. WHITE WALLIS,
Secretary

THE WINGS OF BIRDS[1]

THE power of flying through the air is one of the principal characteristics of the class of birds. Although some members of the other great divisions of the Vertebrates—the bats among Mammals, the extinct pterodactyle among Reptiles, the flying-fishes among Pisces—possess this power in a greater or less degree, these are all exceptional forms, whereas in birds the faculty of flight is the rule, its absence the exception. Among Invertebrates this power is possessed in a very complete degree by the greater number of insects.

In the normal structure of the vertebrate animals there are two pairs of limbs, anterior and posterior, never more. It often happens, however, that one pair, and sometimes both, are suppressed, being rudimentary, functionless, or entirely absent. Flight is always performed by the anterior or pectoral pair, more or less modified for the purpose. The super-addition of wings to arms, as in the pictorial representations of angels, has no counterpart in nature. The wings of the bird, the bat, the pterodactyle, and flying-fish, are the homologues of the arms of man, the fore-legs of beasts. In the flying-fish the power is gained simply by an enlargement of the pectoral fin, and the function is very imperfect; in the pterodactyle, by immense elongation of one (the outer) finger, and extension of the skin between it and the side of the body; in the bats, by elongation of the four outer fingers, and extension of a web of skin between them and the body. In the bird the flying organ is constructed mainly of epidermic structures, peculiar outgrowths from the surface, called *feathers*—modifications of the same tissue which constitutes the hair, horns, scales, or nails of other animals. Feathers are met with only in birds, and are found in all the existing members of the class, constituting the general covering of the surface of the body.

The framework to which the broad expanse formed by the feathers is attached is composed of bones, essentially resembling those of the fore limb of other Vertebrates. The distal segment, manus, or hand, in the vast majority of birds, has three metacarpal bones and digits, the former being more or less united together in the adult state. The digits appear to correspond with the pollex, index, and medius of the typical pentadactyle manus; the second is always the longest. Both it and the pollex frequently bear small horny claws at their extremity, concealed among the feathers and functionless, but very significant in relation to the probable original condition of the avian wing. These claws are altogether distinct from the large, and often functional, spurs developed in many species from the edge of the metacarpal bones, resembling both in use and situation the corresponding weapons in the hind-feet The third digit does not bear a second phalanx or claw in any existing bird.

The quills, remiges, or flight-feathers attached to the bones of the manus (called "primaries"), never exceed twelve in number, and are (as has been recently shown by Mr Wray) in the very great majority of birds distributed as follows:—Six, or in some few cases (flamingo, storks, grebes, &c.), seven to the metacarpus; of the remainder or digital feathers, one (*ad-digital*) is attached close to the metacarpo-phalangeal articulation, and rests on the phalanx of the third digit; two (*mid-digital*) have their bases attached to the broad dorsal surface of the basal phalanx of the second digit, which is grooved to receive them; the remainder (*præ-digital*) are attached to the second phalanx of the same digit. These last vary greatly in development, in fact their variations constitute the most important structural differences of the wing. In most birds there are two; the proximal one well developed, the distal always rudimentary; but the former may show every degree of shortening, until it becomes quite rudimentary, or even altogether absent, as in *Fringillidæ* and other "nine-primaried" birds, in which there are six metacarpal remiges, one ad-digital, two mid-digital, and no præ-digitals, or only a very rudimentary one. The smaller feathers at the base of the quills, called upper and under coverts, have an equally regular arrangement. The webs or vanes of all the flight-feathers are made up of a series of parallel "barbs" which cohere together by means of minute hooklets, and so present a continuous, solid, resisting surface to the air.

Such is the characteristic structure of the wing in almost all carinate birds, whether powerfully developed for flight, as in the eagles, albatrosses, or swifts, or whether reduced in size and power to practically useless organs, as in the extinct great auk, the dodo and its kindred, weka rail, notornis, cnemiornis, &c., most of which, being inhabitants of islands containing no destructive land mammals, appear to have lost the principal inducement, and with it the power, to fly.

In the penguins (*Sphenisconorphæ*) the feathery covering of the wing entirely departs from the normal type. Each feather is like a flattened scale frayed out at the edges, the barbs are non-coherent and have no hooklets. They form an imbricated covering of both surfaces of the wing, including the broad patagium which extends from the cubital side of the limb, but appear to have no definite relation to the bones, and cannot be divided into distinct groups, corresponding to those described above. The structure of the wing separates the penguins sharply from all the other carinate birds.

The Ratitæ, or birds without keel to the sternum, form another very distinct group, distinguished by the rudimentary or imperfect condition of the remiges or quills, which never have coherent barbs, and are therefore unfitted to the purpose of flight. In the ostrich and rhea the bones, though comparatively

[1] Abstract of Lecture by Prof. W. H. Flower, LL.D., F.R.S., at the Royal Institution. February 19, 1886.

small, are distinct and complete, and the feathers large and definitely arranged. The emu, cassowary, and apteryx show various degrees of degeneration, which apparently culminated in the dinornis, no trace of a wing-bone of which bird has ever been found. The question which naturally presents itself with regard to these birds is, whether they represent a stage through which all have passed before acquiring perfect wings, or whether they are descendants of birds which had once such wings, but which have become degraded by want of use. In the absence of palæontological evidence it is difficult to decide this point. The complete structure of the bony framework of the ostrich's wing, with its two distinct claws, rather points to its direct descent from the reptilian hand, without ever having passed through the stage of a flying organ. The function of locomotion being entirely performed by powerfully developed hind-legs, and the beak mounted on the long flexible neck being sufficient for the offices commonly performed by hands, the fore-limbs appear to have degenerated or disappeared, just as the hind-limbs of the whales disappeared when their locomotory functions were transferred to the tail. This view is strengthened by the great light that has been thrown on the origin of the wings of the flying birds by the fortunate discovery of the *Archæopteryx* of the Solenhofen beds of Jurassic age, as in this most remarkable animal, half lizard and half bird, the process of modification from hand to perfect flying bird is clearly demonstrated. The three digits which in the existing forms are more or less pressed together and imperfect, still retain their freedom and complete number of phalanges, and are each armed with terminal claws, while the flight feathers and remiges of the cubital, metacarpal, and digital series are fully developed and evidently functional. The earlier stages in which the outer digits were still present, and the feathers imperfectly formed or merely altered scales, are not yet in evidence.

Some conception of the process by which a wing may have been formed may also be derived from the study of the growth of feathers on the feet of some domestic varieties of pigeons and poultry, illustrations of which were shown at the lecture.

THE SUN AND STARS[1]

VII.

WE have now to endeavour to apply to the more distant stars some of the facts which I have brought before you touching the nearest one—our sun. What we have to do in the short time at our disposal is to choose those facts which will give us the greatest amount of knowledge concerning the greatest number of those stars.

When the star that is nearest to us has set, the number of stars which a pair of eyes can see on a dark night, whether they happen to be north of the equator or south of it—for the number of stars is pretty equally distributed north and south—is something under 3000. But when we leave behind us the power of the unaided eye, and consider what results can be obtained by the optical means now at man's disposal, we have to increase these 6000 to something like forty or fifty millions, so that, if we can by any chance obtain facts touching one star that are applicable to others, we do a great deal. We are, in fact, dealing with 50,000,000 bodies instead of one.

The first thing regarding these distant bodies to which I have to draw attention is that they have been divided for purposes of convenience—astronomical and other—into magnitudes such that the first magnitude means the brightest star we can see; and so we go on till now we go down to the sixteenth magnitude.

The order of diminution of brightness is not quite exact from the first magnitude to the faintest visible to the naked eye, but it may be taken on the average to be about two-fifths. If we take this ratio as the normal one down to the sixteenth magnitude we get the following values nearly:—

$2\frac{1}{2}$	stars 2nd mag.	=	1 star	1st mag.
6	3rd	=	,,	
16	4th	=	,,	
40	5th	=	,,	
100	6th	=	,,	
⋮	⋮			
10,000	11th	=	,,	
⋮	⋮			
1,000,000	16th	=	,,	

[1] A Course of Lectures to Working Men delivered by J. Norman Lockyer, F.R.S., at the Museum of Practical Geology. Revised from shorthand notes. Continued from p. 45.

We not only get the stars thus visible, but, as they can be photographed in a certain period of time, this period measures their photographic brightness. We find, for instance, that a first magnitude star can be photographed in the three-thousandth part of a second; that a star of the seventh magnitude can be photographed in about one second; and when we come to the twelfth magnitude we must turn seconds into minutes, and we shall require two of them to get an impression on the plate; till, working on gradually to the sixteenth magnitude, we find that the photographic plate, which requires only the three-thousandth part of a second for a star of the first magnitude, requires one hour and twenty-three minutes (or eighty-three minutes) to receive the impression, we find the ratio of two-and-a-half times to be practically indicated by the times of exposure.

The relative photographic light of stars of all magnitudes when the most rapid dry plates are used is shown in the following table:—

Magnitude	Time of exposure m.	s.
1st		0·005
2nd		0·013
3rd		0·03
4th		0·08
5th		0.2
6th		0·5
7th		1·3
8th		3·0
9th		8·0
10th		20·0
11th		50·0
12th	2·0	
13th	5·0	
14th	13·0	
15th	33·0	
16th	83·0	

We must not for one moment imagine that, because for many reasons it has been necessary to divide stars into magnitudes, all the stars are of exactly the same size at different distances, or of different sizes at the same distance. We know very little at present relatively. But this we do know, every new fact has shown us that some of the apparently fainter stars may be very large, and some of apparently the brightest stars may be small. You can understand that the light which we get from the stars will depend upon these two things. Take the case of the sun for instance. We know that the sun is a small star, and yet it gives us a great deal of light because it is near to us. We know that some of the other stars are very distant, and they give us a small amount of light, not because they are small, but because they are so far away.

We are living now in a very interesting time, because people are beginning to work here and there, not in too many places, to get the stars to write their own autobiography, so to speak. In fact, a very important attempt is being made at the present moment to replace observations of the positions of the stars by actual photographs. Observations, you know, being human, are always liable to error. This plate, which I am about to show you, is a photograph that I have received from the Brothers Henry of Paris only this morning, showing what photography can do in registering the exact positions and brightnesses of an almost innumerable army of stars by simply exposing a plate in a telescope.

If it is wished to obtain photographs of stars of the sixteenth magnitude, the plate will have to be exposed eighty-three minutes. If we are content to get stars of the seventh magnitude, then two minutes will be enough.

All the stars that you see here are visible in a very restricted portion of the sky in the constellation Cygnus, not very far from the Milky Way. You can understand what a happy thing it will be for the astronomer of the future if, when he wants to know the state of the heavens in this nineteenth century, instead of having to consult musty books of observations which may probably be wrong, he can refer to a book of which the leaves are made of glass, and on which is recorded the autobiography of every square degree of the heavens as you see on this diagram before you.

In our attempt to apply to these other bodies the knowledge which we have acquired touching the sun, of course we have to consider chiefly the light sent to us by them. You will see in a moment that if the sun were very much farther away from us than it really is—imagine it for a moment so far away that

instead of appearing to us with a disk it should appear to us as a star, like Sirius or Capella, for instance—the only difference between its spectrum now and its spectrum then would be that there would be less of it. There would be less light. Consequently it would not be possible for us to see it in all its exquisite detail. But so far as the spectrum went there would be no change in kind, although there might be a change in degree.

Now, if you just assume that for a moment, you see that we shall be in a very fair way to make a very important application of this knowledge, because I was careful to tell you that in the solar system we have indications of a considerable amount of absorption of blue light; so that, if the sun's atmosphere were away and the earth's atmosphere were away, the sunlight, if we are now right in calling it white, would then certainly appear to us as blue, for the reason that the blue light now stopped by the sun's atmosphere and by our own would then be added to the light which we get at the present moment, and the total light therefore received by our eyes would be very much richer in blue rays than it is at present.

Now then, having the fact of this blue absorption in our minds, let us suppose it—to begin with the simplest case—to be enormously increased. Let the blue absorption creep on into the spectrum till at last it reaches the green or the yellow or the red. It is clear that then the sun that we should see would be a red sun, and that sunlight would be no longer white, but red.

Let us next, on the other hand, reduce the quantity of the existing blue absorption. Let us have a solar spectrum as long as the spectrum of the electric light, for instance.

Now let us do something else. Let us suppose that in the solar spectrum, as in very many of the spectra that we can observe in our laboratories, there is superadded to this blue absorption a strong absorption of the red, beginning at the other end of the spectrum. We shall get the yellow and the red, say, absorbed on the one side of the spectrum, while we get the blue and violet absorbed on the other. We shall therefore only get the green light to pass.

Do we get evidence that in the heavens among other stars such conditions as these hold? Certainly. A very considerable number of the stars in the heavens are called coloured stars. They are red, or they are blue, or they are green, for the most part, and you see that simply dealing with the absorption of the blue with which we have become familiar in the case of the sun, playing with it a little, giving it a little rope here, shortening the rope there, and adding another exactly equivalent absorption at the other end of the spectrum, we can at once account simply and sufficiently for the colours of the coloured stars. This is one advantage that we have in working from the known to the unknown. If we had begun with the stars and dealt with their phenomena first, it would have been difficult to explain; but now that we know how a thing happens in the case of the sun, it is quite easy for us to imagine the mechanism which must be at work in the atmosphere of the coloured stars to give us in some cases red suns, in others green suns, and in others still blue suns.

So much then for coloured stars.

There is another matter. As I shall have to show you by and by, one of the most important distinctions between the stars in the heavens is one not depending upon their magnitudes, not depending upon their distances, or upon their mass, or upon anything of that kind, but depending upon conditions which we do not know very much about at present, but which bring about this result, that the spectrum in one case is different from the spectrum in another, exactly as in our laboratories we find the spectra of bodies with which we are perfectly acquainted become different if the temperature which we employ is made to differ. For instance, in the case of the vapour of carbon we may employ a low temperature, and get a certain spectrum of the vapour which is called a spectrum of flutings. If we increase the temperature, and then again observe, the flutings have disappeared. They have given way to a system of lines in which the irregularity is just as striking as the exquisite rhythm of the flutings was in the former case. From hundreds of these observations the student of spectrum analysis is not afraid to say that when he sees a spectrum of flutings he knows that he is dealing with the action of vapours at a much lower temperature than exists in those conditions in which the flutings are replaced by lines. And, more than that, so definite is this, so much do we know about the fluted spectra of those substances which exist in the solar atmosphere—giving us, at the temperature of the sun, the line spectrum—that it is easy for us to take the responsibility also of saying that, if the sun's atmosphere were to be suddenly cooled to-morrow, we should get a spectrum of flutings, instead of a spectrum of lines; so that when we get, if we do get, the fluted spectrum in the spectrum of a star, we are justified in saying that some cause has been at work in that star equivalent to a cooling process in the atmosphere of our own star. Thus, if we cooled the sun to-morrow we should produce the spectrum of flutings, and as in cooling down the sun will in all probability pass through a stage indicated by flutings, so also while it was acquiring its present temperature it passed through the same stage.

What, on the other hand, would happen if we had the sun very much hotter to-morrow? It is important to think this out very carefully. According to the views which I have brought before you, we have, outside all, solids absorbing every part of the spectrum. Then we have liquids and dense vapours doing the same: less dense vapours absorbing the red, and finer vapours still absorbing the blue. We have flutings also, but chiefly we have vapours at an enormous temperature which give us the familiar absorption spectrum of Fraunhofer lines.

We have the Fraunhofer spectrum in short giving us the summation of the line absorption of every stratum in the sun's atmosphere. We have also a wonderfully simple spectrum of the chromosphere, of which I gave you the list of lines, writing down for us the absorption of the hottest part of the sun's atmosphere that we can get at.

Now try to think this out quite completely.

The first obvious thing which will strike us is that, if the sun could be made hotter to-morrow than it is to-day, the thing that we should be quite certain about, whatever might happen to the other conditions, would be that the gases which give us that simple spectrum of the chromosphere would have a larger share in the absorption-spectrum, and that therefore the absorption-spectrum of the star would gradually get nearer and nearer to the absorption-spectrum which would be given by the chromosphere itself if it could be seen in all its simplicity. I think that way of reasoning is right. Well, if you think it is, you will find that it will lead us to a very interesting conclusion. If we find any star with practically the spectrum of the chromosphere, we shall be bound to admit that the atmosphere of that star must be hotter than the *average* temperature of the atmosphere of our sun as its spectrum approaches that of the *hottest* part of the sun's atmosphere.

There is one other point that I have to bring before you before I go further, and it is this. We have had a great deal to say about the photosphere of the sun and the surrounding envelopes. We saw that when any vapours were located between our eye and the bright sun in the centre we then got absorption-lines, for the reason that the sun was hotter than the vapour on this side of the sun, so to speak, and therefore light was stopped by the cooler vapour in the atmosphere, and we got a dark line. The moment however, we work outside the disk, and study a prominence on the limb of the sun, or even a part of the corona, we observe them by means of their bright lines—by means of their radiation. There is no hotter light source behind them, and therefore we deal simply with radiation.

Now, that being so, you will understand how it is that in the general spectrum of the sun all the lines are dark, because we found that while the bright central part of the sun was not very much less than the whole volume, something like a tenth, it was very much hotter, so that we get many thousand times more light from the centre of the sun. If a substance in the outer atmosphere gives us a bright line corresponding with a dark line given us from this central portion due to the atmospheric absorption, all it can do is to reduce the intensity of the dark line produced by the intensely illuminated central portion.

It is a question of area. The difference of area is small, smaller than the difference of illumination, and therefore anything which happens outside does not get its record written at all, the area being five or six to one, and the intensity of the light in the centre being, say, ten thousand to one.

Now let us consider another case. Let us suppose that there is a star (never mind which it is) the atmosphere of which is so enormous that its diameter to the diameter of the central photosphere is represented by two concentric circles—one very large, the other very small. Here the difference of area between the inner circle, which gives us dark lines, and the larger exterior space, which gives us bright lines, if it gives us anything, is so enormous that it may be greater than the difference of the intensity of the light; so that if the inner light is ten times brighter than the light which comes from the outer

area, which, let us say, is a couple of hundred times greater, in that case we shall be bound to have bright lines from the exterior regions mixing with the dark lines coming from the interior regions. Hence we see that the spectra which we may get from stars will not depend upon the diameter of the stars at all, but may depend upon the difference of area simply which we should get by cutting a section at right angles to the line of sight from the earth through the star and its whole atmosphere.

It comes to this: Suppose some stars have very large coronal atmospheres; if the area of the coronal atmosphere is small compared with the area of the section of the true disk of the sun, of course we shall get an ordinary spectrum of the star; that is to say, we shall get the indications of absorption which make us class the stars apart; we shall get a continuous spectrum barred by dark lines. But suppose that the area of the coronal atmosphere is something very considerable indeed, let us assume that it has an area, say fifty times greater than the section of the kernel of the star itself; now, although each unit of surface of that coronal atmosphere may be much less luminous than an equal unit of surface of the true star at the centre, yet if the area be very large, the spectroscopic writing of that large area will become visible side by side with the dark lines due to the brilliant region in the centre where we can study absorption; other lines (bright ones) proceeding from the exterior portion of that star will be visible in the spectrum of the apparent *point* we call a star.[1]

Those things, then, being premised, we are now in a position to approach the subject of stellar spectra. Much work is now being done in this direction, but we must not forget the early workers. We must not forget that it was Fraunhofer at the beginning of this century who first saw and carefully observed several spectra of stars, and we must be all the more careful to remember that, since really more than half a century passed before anybody took the trouble either to repeat his observations or to extend them. Some twenty years ago, however, several observations had been brought together by the labours of Italian and American men of science (scarcely a stellar spectrum had been observed in England). This enabled a distinguished American, Mr. Rutherfurd, to begin to put a little order into the facts which had so far been acquired.

He pointed out that it was easy to arrange these stars into classes—that all the spectra were not alike. There was a wonderful family likeness among three groups of them, and he showed that you might divide these spectra into three very definite classes. After him came two countrymen of our own, Dr. Huggins and Dr. Miller, who, when they did begin their work, certainly put into it an amount of vigour and assiduity which had never been approached before their time. They not only gave us careful drawings of the spectra of the stars which they

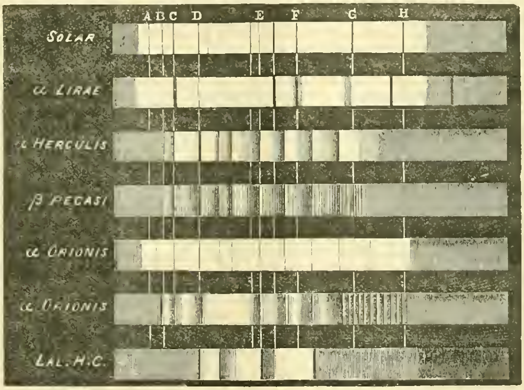

FIG. 21.—Various types of stellar spectra.

observed, but with infinite care and patience they made comparisons, as we may say, to determine the origin of the lines in exactly the same way as I have pointed out that Kirchhoff, Ångström, and Thalén discovered the origin of the lines in the spectrum of the sun. Indeed, they did not rest here, or rather, one of them did not rest here, for Dr. Huggins subsequently introduced a system of photography, and now, thanks to his skill, we have several photographs, of priceless value, of some of the brighter stars. And while I am lecturing to you here in London there is one observer in Berlin, Dr. Vogel, and another in the north of Europe, Dr. Dunop, doing all they can to give us a complete and perfect spectroscopic catalogue of every star that shines in the northern heavens, so that you can see that the work is going on.

Now, before I say any more about it, I will refer to a diagram which gives an idea of the kind of thing that one sees when these observations are being made.

We will just run through them one by one. There is a very rough and general view of the spectrum of the sun. The actual spectrum of the sun has been thrown on the screen before you, and therefore it will be quite understood that there we have a very rough copy of it for diagrammatic purposes, indicating merely the most obvious among the Fraunhofer lines. When we pass from the sun to α Lyræ, we pass from a star having a relatively large number of lines to one having a small number; and this small number of lines is further remarkable from the fact that the lines are much thicker than those seen ordinarily in the solar spectrum. Keeping to the stars which give us spectra of lines, here in α Orionis we get another case in which the lines do not occupy the places occupied by lines in the spectrum of the sun, nor, at the same time, are they so thick as the lines in stars of the Lyra type. We can also learn from this diagram, by the examination of the spectra of α Herculis and β Pegasi, that we get flutings from stars as well as lined spectra. We also see that these flutings are not all exactly in the same place, by which we can infer that the flutings are not all probably of the same chemical origin. Of that further by and by. The use of the diagram is to give a general idea. J. NORMAN LOCKYER

SCIENTIFIC SERIALS

The American Journal of Science, June.—The Biela meteors of November 27, 1885, by H. A. Newton. From a general survey of the observations made in various places, the author infers that the maximum of the shower was about 6h. 15m. Greenwich mean time; that the total hourly number of meteors visible at one place in a clear sky was at the utmost 75,000; that the densest part of the stream was not over 100,000 miles in thickness; that the meteors of November 27,

[1] *Proc.* Roy. Soc., No. 185, 1878.

1872 and 1885, did not leave the immediate neighbourhood of the Biela comet earlier than 1841-45, and may be treated as having at that time orbits osculating that of the comet.—The ultra-violet spectrum of cadmium, by Louis Bell. The ultra-violet spectrum of cadmium having long served as a standard of reference in the measuring of other spectra, an attempt is here made to determine its principal wave-lengths more accurately than is possible by Cornu's ingenious process. By taking photographs on Stanley instantaneous dry plates, Mr. Bell believes the wave-lengths here determined will be found correct to probably within 1/50,000 part of their respective values. The total number of lines accurately determined in the entire spectrum was thirty, of which the wave-lengths are tabulated with the corresponding figures obtained by Hartley and Cornu.—Communications from the United States Geological Survey, Rocky Mountains Division. The present communication (No. vii.) deals with the occurrence of topaz and garnet in lithophyses of rhyolites, and is contributed by Mr. Whitman Cross, who had already described the occurrence of minute crystals of topaz in the small drusy cavities of a coarsely crystalline rhyolite from Chalk Mountain, by Fremont's Pass, Colorado. The present specimens of topaz and small dark red garnets are from the trachyte on the Arkansas River, opposite Nathrop, Chaffee County, Colorado. The mode of formation of the topaz and garnet in the lithophysal cavities of the rhyolite in this district is not fully determinable, but they are evidently not secondary, but primary products, produced by sublimation or crystallisation from presumably heated solutions contemporaneous, or nearly so, with the final consolidation of the rocks.—On the strain-effect of sudden cooling exhibited by glass and by steel, by C. Barus and V. Strouhal. The experiments here described confirmed the views already announced by the authors, that the annealing of steel, considered physically, is at once referable to the category of viscous phenomena; also that the existence of the characteristic strain in glass-hard steel is the cause of electrical effects so enormous, that any additional effects caused by any change of carburation may be disregarded, and the electrical and magnetic results interpreted as due to variations in the intensity of the said strain. The chief results here arrived at have since been substantiated by polariscope evidence and by the investigation of the density of the consecutive shells of the "Prince Rupert drop." An account of these results will be given in their next paper.—Upon the origin of the mica-schists and black mica-slates of the Penokee-Gogebic iron-bearing series, by C. R. Van Hise. The iron-bearing formation of this region extends for over 80 miles from Lake Numakagon in Wisconsin to Lake Gogebic in Michigan; and at Penokee Gap, Wisconsin, the series is 13,000 feet thick, the upper 11,000 feet being mica-schists and black slates. The Muscovitic and biotitic greywacke, biotite-schists, and other formations here described furnish a graded series from the slightly altered greywackes to the crystalline mica-schists.—On two masses of meteoric iron of unusual interest, by Wm. Earl Hidden. One of these specimens, found on July 2, 1885, on a height to the east of Batesville, Independence County, Arkansas, weighs 94 lbs., and belongs to the class holosiderite of Brezina. It is specially remarkable for a hole piercing it near the edge, and cone-shaped from both sides. Analysis yielded: iron, 91·22; phosphorus, 0·16; nickel and cobalt, 8·62 by difference. The other, found in 1857 in Laurens County, South Carolina, weighs only 4 lbs. 11 oz., but is noted for the perfection of the Widmanstätter lines and unusual abundance of nickel and cobalt. Analysis: iron, 85·33; nickel, 13·34; cobalt, 0·87; phosphorus, 0·16, with trace of sulphur.—Notice of a new genus of Lower Silurian Brachiopoda, by S. W. Ford. This nearly perfect specimen of the ventral valve of the species described by E. Billings under the name of *Obolella desiderata*, and now preserved in the collection of Walter R. Billings, Ottawa, may be taken as the type of a new genus, probably including several described Lower Silurian species. It differs from *Obolella* in the form and arrangement of its muscular impressions, in the possession of a thinner shell and in other respects. The author, therefore, proposes for it the new generic name of Billingsia in honour of Mr. E. Billings, the late eminent palæontologist of the Canadian Geological Survey.

Bulletin de l'Académie Royale de Belgique, April 3.—Determination of the remainder in Gauss's quadrature formula, by M. Mansion. By a definite integral the author completes this formula, which thus becomes applicable to non-parabolic curves.—On some remains of cetaceans from the foot of the Caucasus, by M. P. J. Van Beneden. These remains, comprising portion of a skull with some vertebræ from the district east of Vladikavkas, and an almost perfect vertebral column, with ribs, radius, and humerus from the bed of the Kuban River, all belong to the same species, the *Cetotherium rathkei*, Brandt. By their means the author is enabled to determine the true characteristics of the Cetotherium, which shows some affinity to the Pachyacanthæ of the basin of the Danube, but was quite distinct from the extinct species of the Antwerp basin.—On some rocks dredged off the Ostend coast, by M. A. F. Renard. These include granites, porphyries, diorites, &c., such as occur along the French seaboard and in the Channel Islands; also Jurassic and Chalk formations identical with those of Boulogne and the cliffs of Dover. There is nothing to show that any of these rocks have been transported either from the south or from the Scandinavian regions during the Glacial epoch.

Bulletin de la Société des Naturalistes de Moscou, 1885, No. 1.—Revision of the numerical values of the repulsive force, by Prof. Th. Bredichin. In his preceding researches the author had determined it approximately by means of the rough formula of Bessel. Now, he corrects these results, either by direct evaluations by means of more exact formulæ, or indirectly by means of the isodynames constructed upon his rigorous formulæ. Taking 40 different comets (since 1472) M. Bredichin classifies them under three different types, and, on the former method, receives for the first type, $R = 14$, while the initial speed (due to the ejective force) varies between $g = 0·1$ and $g = 0·34$, the average being 0·22; for the second type, $R = 1·1$, and $g = 0·05$ (varies between 0·03 and 0·07); and for the third type, $R = 0·2$, and $g = 0·1$ to 0·2.—On the oscillation of the emissive of comets, by the same (with a plate). From a careful study of the comet 1862 III. the learned professor concludes that the oscillations of its emission ought to be considered beyond doubt, as they result not only from measurements, but also from all the *ensemble* of phenomena afforded by the head and tail of the comet.—Third report upon my herbarium, by Ed. Lindemann (in German).—Plantæ Raddeanæ Monopetalæ (continuation of Labiatæ), by Ferd. Herder.—Letters from Dr. A. Regel dated from Bokhara, Merv, &c., between May 1884 and April 1885.—Notice of a journey to Akhal-Tekke, by A. Becker, with a list of plants found at Kyzyl arvat.—On northern *Aucellæ*, by H. Trautschold.

No. 2.—Enumeration of the vascular plants of the Caucasus, by M. Smirnoff, continued from the preceding issue, and forming an introduction to the flora of the Caucasus.—Birds of the Transcaspian region, by M. Zaroudnoi.—Thirty-five years of observations on the earliest and latest times of blooming of wild and cultivated plants in the neighbourhood of Kishineff, by A. Dœngingk, followed by remarks on vegetable parasites and noxious insects. Four hundred plants are on the lists of the author.—Revision of the copulatric armatures of the males from the *Philecemide* tribe, by Gen. Radoszkowski (with two plates).—The appendix contains the third part of the systematic catalogue of the herbarium of Moscow University, published by Prof. Goroshankin.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 13.—"On the Structure of Mucous Salivary Glands." By J. N. Langley, M.A., F.R.S., Fellow and Lecturer of Trinity College, Cambridge.

The cells of mucous salivary glands I have previously described as consisting of a framework or network, containing in its spaces hyaline substance and granules. The granules of the mucous salivary glands are rendered very distinct by irrigating a mounted specimen of a fresh gland with moderately dilute solutions of neutral or alkaline salts. In these fluids the granules can scarcely be distinguished from small fat globules; those of the submaxillary gland of the dog have a diameter of 1 to 2 μ. In the resting gland the granules are fairly closely packed throughout the cell, in a line stretching from basement membrane to lumen; there are 8 to 12 granules. Both hyaline substance and granules give rise to mucin.

During secretion both the hyaline substance and the granules are turned out of the cells; after prolonged secretion the cells consist of an outer zone, chiefly of freshly-formed substance, and of an inner zone of network, hyaline substance, and granules, as in the resting state. When the saliva has a high percentage of

solids, both the hyaline substance and the granules can be seen in it. The hyaline substance is more soluble than are the granules, and is thus less commonly seen; it is partly dissolved, partly swollen up into a continuous mass; the less swollen parts appear as strings or blebs. The granules in saliva vary greatly in appearance; they may be very slightly swollen, and have fairly sharp outlines; or they may be more swollen and run together, forming pale masses of various size; occasionally in more dilute saliva they are just visible as pale spheres.

Although the mucous cells are able to turn out bodily their products, they do not disintegrate during secretion. As the decrease in the interfibrillar substance takes place, there is a fresh formation of substance in the outer part of the cells, *i.e.* as the cell secretes it also grows. In saliva there is no evidence of broken-down cells, nor are nuclei present except those in "salivary corpuscles," which, as stated by Pflüger, are leucocytes. Further, there is not any satisfactory proof that the demilune cells multiply during secretion, and give rise to mucous cells. During secretion there is no increase in the number of nuclei undergoing indirect division. As I have previously said, I hold the demilunes to be secreting cells of a different nature from that of the mucous cells. Glands with demilunes are simply glands in which the "albuminous" element is reduced to a minimum. The apparent increase in size of the demilunes, described by Lavdowsky as taking place in the first stage of secretory activity, I take to be due to the decrease in the size of the alveoli, so that the ordinarily flat demilunes become more spherical. Moreover, the demilune cells show signs of secretory activity. The "young" cells described by Heidenhain and by Lavdowsky are chiefly altered mucous cells.

The network of the cell consists of two parts—one in the cell-membrane, the other stretching from this throughout the cell. The peripheral network consists of very delicate fibres; at some of the nodal points there are small spherical swellings. From lumen to basement membrane there are twelve to fifteen meshes. The internal network is connected with the peripheral network, but it appears to me to have much larger meshes. From basement membrane to lumen there are in the submaxillary gland of the dog four to six meshes, *i.e.* the number of meshes in a given direction in the cell is about half that of the number of granules.

May 27.—"A General Theorem in Electrostatic Induction." By John Buchanan, B.Sc.

Part I. of this paper deals with the effect of change of the specific inductive capacity of a dielectric which is placed in a field of electric force, and it is proved that in general, under these circumstances, the dielectric becomes electrified.

By translating the theorem into the language of magnetism a theorem in magnetic induction is obtained.

The mathematical proof leads to an expression of the form

$$h = -\left(\frac{d\pi}{dV} - V\frac{d^2\pi}{dV^2}\right),$$

where h denotes the rate of change of the apparent electrification of the dielectric with regard to the specific inductive capacity as independent variable; π denotes the rate of change of the work done against electrical forces with regard to the same independent variable; and V denotes the potential.

The conditions that there may be no electrification of the dielectric are next obtained. The result is arrived at that, in order to have no electrification, when the specific inductive capacity is altered, the whole field of force must be occupied by an electrically homogeneous dielectric. It is then pointed out that the equations obtained express the effect of heterogeneity in the constitution of the dielectric medium.

In Part II. the above theorem and some of the results obtained by Dr. Kerr in his experiments in "electro-optics," are applied to obtain a theory of electrification by friction.

The discussion leads to these conclusions:—

"Positive" liquids tend to become positively electrified by friction.
"Negative" ,, ,, negatively ,, ,,
"Positive" solids ,, negatively ,, ,,
"Negative" ,, ,, positively ,, ,,

All these conclusions are verified by the experimental results given in the paper.

June 10.—"Fluted Craterless Carbons for Arc Lighting." By Sir James N. Douglass.

On December 8, 1858, at the South Foreland High Lighthouse, and with the direct current magnetic machines of Holmes, the first important application of the electric arc light, as a rival to oil and gas for coast lighting, was carried out by the Trinity House, under the advice of Faraday.

The carbons then used, and for several years afterwards, were sawn from the residuum carbon of gas retorts; they were square in section, $6\frac{1}{4} \times 6\frac{1}{4}$ mm., and the mean intensity of the arc measured in the horizontal plane was 670 candle units, being 17 candle units per square millimetre of cross-sectional area of the carbon. The crater formed at the point of the upper carbon of the "Holmes" lamp was so small that no appreciable loss of light was found to occur, and the arc proved to be very perfect in affording an exceptionally large vertical angle of radiant light for application with the optical apparatus.

The most reliable and efficient machine that has yet been tried for lighthouse purposes is the large size alternate current magneto machines of De Meritens. The average results with these machines are as follows, viz.:—

	One machine	Two machines supplying current to one lamp
E.M.F.	38 volts	48 volts.
Mean current	206 amperes	372 amperes.
Carbons (cylindrical) ...	35 mm. diam. ...	50 mm. diam.
Diameter of crater in carbon	13 mm.	18 mm.
Mean intensity of arc measured in the horizontal plane (candle units) ..	15,000	30,000
Light per square millimetre of carbon section (candle units)	12	12

It will be observed from this statement that the intensity of the arc in the horizontal plane per square millimetre of sectional area of carbon is about 35 per cent. less than it was with the small square carbons used by "Holmes," although it might reasonably be expected that with the improvements since effected in the manufacture of carbons, the efficiency of the old carbons would at least be maintained. The relative inefficiency of the large carbons used with the powerful currents now available appears to be due (1) to the loss of a large portion of the most intense part of the arc which is confined within the crater of each carbon; and (2) to the fluctuations in the intensity of the arc caused by the current passing between various points of the end of each carbon.

For a new electric light installation about to be made by the Trinity House at St. Catharine's Lighthouse, Isle of Wight, it is intended to utilise the large De Meritens machines that were used at the recent South Foreland experiments for determining the relative merits of electricity, gas, and oil as lighthouse illuminants. The electric light at St. Catharine's is intended to be "single-flashing" at periods of 30 seconds. Each flash is to have a duration of $5\frac{1}{2}$ seconds, and to be followed by an eclipse of $24\frac{1}{2}$ seconds. It is intended to use one De Meritens machine during clear weather, and two machines whenever the atmosphere is found to be so impaired for the transmission of light that the flashes are not reaching their intended range.

The defect here arose which is common to all electric flashing lights where a minimum and a maximum intensity of flash are adopted, viz. that the duration of the flashes of minimum and maximum intensity would vary in the ratio of the difference in the diameter of the carbons employed with one and two machines respectively, which in this case should be 50 mm. and 35 mm., this mean difference amounting to $36\frac{1}{2}$ per cent. nearly. It is evident that such a variation in the duration of flash would seriously impair the distinctive character of the signal.

It occurred to me, however, that, if carbons of a fluted cross-section were employed, the carbons for minimum and maximum intensity could be made of corresponding diameter, their sectional areas being proportioned to the minimum and maximum currents employed, and thus the flashes of minimum and maximum intensity would have exactly the same duration. As all carbons for electric arc lights are now made in moulds, I saw that such a form would not involve any more difficulty in manufacture than if made cylindrical, while there would be less liability of internal fracture occurring, as is often the case with large carbons in the process of drying and baking. Other advantages to be obtained with fluted carbons are: (1) a larger vertical angle of radiant light from the arc, and with a higher coefficient of in-

tensity in consequence of the unobstructed radiance through the fluting at the points of each carbon; and (2) a steadier light is obtained owing to the localising of the current at the central portion of each carbon.

The result of many experimental trials with fluted carbons 50 mm. diameter have entirely confirmed my expectations. No crater is formed in either of the carbon points, and their form is all that can be desired for utilising fully the maximum light of the radiant arc. My experiments have not been sufficient to determine accurately the additional intensity of light obtained from the arc of a pair of the fluted carbons as compared with that from the arc of a pair of cylindrical carbons, but I am of opinion that the gain with fluted carbons is not less than ten per cent.

Geological Society, June 9.—Prof. J. W. Judd, F.R.S, President, in the chair.—The following communications were read:—On the volcanic rocks of North-Eastern Fife, by James Durham, F.G.S., with an appendix by the President. After describing the general distribution of the volcanic rocks of Old Red Sandstone and Carboniferous age in the counties of Forfar and Fife, the author called attention to a fine section exhibited where the Ochil Hills terminate along the southern shore of the Firth of Tay. In immediate proximity to the Tay Bridge, a series of the later volcanic rocks, consisting of felstones, breccias, and ashy sandstones are found let down by faults in the midst of the older porphyrites (altered andesites) which cover so large an area in the district. The breccias contain enormous numbers of blocks of a red dacite (quartz-andesite), and inclosed in this rock angular fragments of a glassy rock, resembling a "pitchstone-porphyry," are found, everywhere, however, more or less converted into a white decomposition-product. The youngest igneous rocks of the district are the bosses and dykes of melaphyre (altered basalt and dolerite) which have been often so far removed by weathering as to leave open fissures. In the appendix three very interesting rocks were described in detail. The rock of the Northfield Quarry, which is shown to be the augite-andesite, has a large quantity of a glassy base with felted microlites, and contains large porphyritic crystals of a colourless augite. The rock of the Causewayhead Quarries is described as an enstatite-andesite; it has but little glassy base, being made up of lath-shaped felspar crystals (andesine), with prismatic crystals and grains of a slightly ferriferous enstatite; there are no porphyritic crystals, but the enstatite individuals are sometimes curiously aggregated. The red porphyritic rock from the breccias near the Tay Bridge was shown to be a mica-dacite, and the glassy rock associated with it to be the same material with a vitreous in place of a stony base. The glassy base exhibits very beautiful fluidal and perlitic structures. The crystals of first consolidation in this rock are oligoclase and biotite, often showing marks of injury in transport; those of the second consolidation appear to be orthoclase. In conclusion, the successive stages by which the andesitic rocks of the area were altered, so as to assume the characters distinctive of porphyrites, were fully discussed, as well as the change of the glassy rock into its white decomposition-product.—On some eruptive rocks from the neighbourhood of St. Minver, Cornwall, by Frank Rutley, F.G.S. The rocks described in this paper were derived from Cant Hill, opposite Padstow, and from a small quarry about half a mile from Cant Hill, near Carlion. At the former locality the volcanic rocks are much decomposed, but from their microscopic characters they may be regarded as altered glassy lavas of a more or less basic type. No unaltered pyroxene, amphibole, or olivine is to be detected in the specimens described, but there is a considerable amount of secondary matter which may include kaolin, serpentine, chlorite, palagonitic substances, &c. There is evidence of fluxion-structure in some of the sections; others are vesicular, and the vesicles are usually filled with siliceous or serpentinous matter. The relation of these lavas to the underlying Devonian slates was not ascertained. The rock occurring near Carlion contains numerous porphyritic crystals of augite in which the crystallisation is interrupted by the co-development of small felspar crystals, which appear, as a rule, to have been converted into felsitic matter. Ilmenite is also present in patches which indicate a similar interrupted crystallisation to that shown by the augite. The rock has the mineral constitution of an augite-andesite, but since it is a holocrystalline rock, exception would be taken by many petrologists to the employment of the term andesite. The lavas of Cant Hill were also probably of an andesitic character, so that, so far as original mineral constitution is concerned, there is some apparent justification for the mapping of both of these rocks as "greenstone" by the Geological Survey.—The Bagshot beds of the London Basin, by H. W. Monckton, F.G.S., and R. S. Herries, B.A., F.G.S. The authors stated that their object was to describe more fully the Lower Bagshot beds, and to disprove the view lately advanced by Mr. Irving that, in certain places, the Upper Bagshots overlap the Lower, and rest directly on the London Clay. They described or referred to a number of sections all round the main mass, beginning at St. Ann's Hill, Chertsey, where they considered that the mass of pebbles and associated greensands must be referred to the Middle Bagshot. The outliers near Bracknell and Wokingham were shown to consist of Lower and Middle Bagshot, which does not appear in the valley north of Wellington College. The Aldershot district was explained, and it was shown that the beds there resting on the London Clay were Lower and not Middle Bagshot, and the occurrence of fossils in the Upper Bagshot of that district was recorded. The conclusions that the authors came to were, that a well-marked pebble-bed was almost always present, marking the division between the Upper and Middle Bagshots, but that there were other pebble-beds of a less persistent character occurring both in the Middle and Lower Bagshots; that the Lower Bagshots generally consist of false-bedded sands with clay laminæ and no fossils except wood, whereas the Upper Bagshots are rarely false-bedded, and are characterised by the absence of clay bands and the presence of marine fossils; and that the Middle Bagshot is a well-marked series consisting of greensands and clays. They claimed, in conclusion, that there was no reason for disturbing the old reading of the district, and that there was no evidence of an overlap of the Lower Bagshots by the Upper.

Physical Society, June 12.—Dr. J. H. Gladstone, Vice-President, in the chair.—Dr. Samuel Rideal and Mr. E. C. Wellington were elected Members of the Society.—The following communications were read:—On an electric-light fire-damp indicator, by Messrs. Walter Emmott and William Ackroyd. The Royal Commission on Accidents in Mines point out in their recently-issued report, as a serious objection to the use of the electric light in mines, notwithstanding its many great advantages, that the light of an incandescent lamp, being produced within a vacuum, cannot admit of any device for the indication of fire-damp such as is given by the Davy, for example. The present apparatus is the outcome of an attempt to overcome this difficulty. It consists of two incandescent lamps, one with colourless and the other with red glass, and the circuit is so arranged that in an ordinary atmosphere the colourless lamp alone shines, but in fire-damp this goes out, and the red one is illuminated. This is effected in a simple manner by the motion of a mercury contact occupying the lower part of a curved tube, one end of which is open, and the other connected with a porous pot of unglazed porcelain, the motion of the mercury being due to the increased pressure in the porous pot occasioned by diffusion.—On a method of distinguishing rays of solar from those of terrestrial origin, by Prof. Cornu. It has been shown by M. Fizeau that, owing to the rotation of the sun upon its axis, there is a displacement of the spectral lines produced by solar absorption towards the red or towards the violet, according as to whether the light examined emanates from those parts of the sun which are receding from or approaching us. If, however, the lines are the result of absorption by the earth's atmosphere no such displacement should occur. It has been the aim of the author to make this principle the basis of a simple and instantaneous method of determining the origin of any given line. The displacement is very minute, amounting to about 1/150 of the distance between the D lines for rays in that part of the spectrum when the light is from the extremity of the solar equator, but it has been found quite sufficient. Observations have been made with a Rowland grating, the mean distance of the lines being ·00176 mm. An image of the sun is formed upon the slit of the spectroscope by a lens. By a slight oscillatory motion given to the lens by a lever from the hand, any part of the sun's image can be brought upon the slit. A heliostat sends the rays always in the same direction, and by a prism the image has its equator horizontal. To distinguish between a line of solar and one of terrestrial origin the line is brought near the vertical wire of the eye-piece, or, better still, one of those inevitable grains of dust which are always seen on the horizontal wire. The lever connected to the lens is then oscillated so as to bring alternately the two ends of the solar equator tangentially upon the slit. If the ray is of terrestrial origin it remains abso-

lutely fixed, if it is solar it oscillates with the lever.—On a hyperbolagraph, by Mr. H. H. Cunnynghame. It is not an unfrequent want to be able to find a rectangle of greatest or least area contained between a curve and rectangular co-ordinate axes. In several problems connected with motion and pressure in steam-engines this is useful, and even in political economy the graphic representation of monopoly curves depends on maxima and minima of this nature. For the solution of such problems it is often very useful to be able to describe rectangular hyperbolas, and the author has devised a machine to effect this. It depends on a mathematical property of the rectangular hyperbola, which he believes to be new, and which is as follows: From a fixed point let any line be drawn to meet a fixed line, and from the point of meeting draw the line perpendicular to the fixed line, and equal in length to the first line. The locus of the extremity of the second line is a rectangular hyperbola, or if from a fixed point O a line OP be drawn to meet a fixed line in a point P, and PQ be taken perpendicular to the fixed line, so that $OP + OQ$ be constant, then again the locus of Q is a rectangular hyperbola. In the machine the latter construction is mechanically and continuously carried out. A pencil, whose point corresponds in position to the point Q, slides along a rule which is carried across the paper always perpendicularly to the fixed line. A fine steel wire attached to the pencil passes over round a roller at P, and is then carried to and coiled round a similar one at O. The use of a steel wire is a special feature of the apparatus, and has a great advantage over string, which, owing to the facility with which it stretches, cannot give good results. The finest wire should be used: it unrolls f om the one roller as much as it laps over the other, and its use may be extended to nearly all curve-drawing machines.—A voltaic cell with a solid electrolyte was exhibited by Mr. Shelford Bidwell. Its construction is as follows: upon a plate of copper is spread a layer of quite dry precipitated sulphide of copper; if on this a clean plate of silver is placed, and the cell joined up to a galvanometer, a slight deflection is observed due to the unavoidable presence of moisture. If, however, the silver plate be covered with a slight film of sulphide of silver, by pouring on it a solution of sulphur in bisulphide of carbon and evaporating the free sulphur by heat, and then placed with the prepared side down as before, a deflection is obtained far greater than, and in the opposite direction to, the former. The resistance of the cell was very great, but was enormously reduced by compression; the E.M.F. was about ·07 volt.

Mineralogical Society, May 21.—Prof. M. F. Heddle, M.D., F.R.S.E., in the chair.—The following papers were read:—On the nomenclature of the hydrocarbon compounds, with a suggestion of a new classification, by Andrew Taylor, F.C.S.—On new localities for diatomite, by Prof. W. Ivison Macadam.—On new localities for the mineral agalmatolite, with notes on its composition, by W. Hamilton Bell.—On a new locality for agalmatolite, with analysis, by Prof. W. Ivison Macadam.—The metallic ores of Chilé, by John F. Kerr, illustrated by a splendid collection of specimens.—On the chemical composition of the mineral found by Mr. Wallace at Loch Bhruithaich, Ross-shire, by Prof. W. Ivison Macadam.—Note on serpentine from Creag Mhòr Thollie, Loch Maree, by Prof. W. Ivison Macadam.—Notice of mica trap from Farley, near Beauly, by T. D. Wallace.—An excursion was made in the afternoon to the Spindle and Buddo Rocks, under the guidance of Prof. Heddle.

Edinburgh

Royal Society, June 21.—Sheriff Forbes Irvine, Vice-President, in the chair.—Mr. Omond, of Ben Nevis Observatory, read a paper on the diurnal variation in the direction of the summer winds on Ben Nevis. These varying winds seem to be entirely local, and are caused by the heating of the one side of the mountain by the sun, while the other is cooled by radiation. The air consequently passes over the mountain from the hot to the cold side.—Mr. A. Buchan read a paper on the meteorology of Ben Nevis. He referred chiefly to three points:—(1) temperature-variation; (2) variation of barometric pressure; (3) wind-speed. As regards temperature, there is the usual morning minimum and afternoon maximum, which tend to be obliterated in the winter months. The barometer reads below average in the early morning, and above average in the afternoon. There is an afternoon minimum, which tends to disappear in summer. The wind-speed is below average during the night, and above average in the afternoon. The barometer reads low when the wind is high at the top of the mountain. Mr. Buchan pointed out that the great advantage of the Observatory is that simultaneous observations are made at the top of the mountain and at the foot, the station at the foot being on an incline sloping down to sea-level. If this latter condition is not satisfied, no reliance can be placed upon deductions from the results obtained as to the rate of diminution of temperature with height. The Observatory at Hong Kong is so conditioned, and the rate of diminution, as deduced from results obtained there, is 1° F. per 281 feet. From the Ben Nevis observations Mr. Buchan finds it to be 1° F. per 270 feet.—Mr. G. W. W. Barclay described some algoid lake-balls found in South Uist.—Dr. W. Hunter read a paper on the duration of life of the red blood-corpuscles, as ascertained by transfusion. Three weeks is the average period given by his experiments. When there is no devitalising action in the corpuscles by the method of observation employed, it is probably from three to four weeks.

Paris

Academy of Sciences, June 21.—M. Jurien de la Gravière, President, in the chair.—Improvement of the bar at the mouth of the Senegal River, by M. Bouquet de la Grye. Having studied the question on the spot during the year 1885, the author proposes some simple measures by which the dangerous effects of the bar might be obviated and the navigation of the Senegal waters greatly improved.—On some double phosphates of thorium and potassium or of zirconium and potassium, by MM. L. Troost and L. Ouvrard. By preparing a certain number of phosphates of thorium and the corresponding compounds of zirconium by the dry process, the authors have endeavoured to verify the analogy pointed out by several observers between thorine and zircon. They find that the metaphosphate and the pyrophosphate of potassa yield with thorine and zircon double phosphates which have analogous compositions, but are not isomorphous. The orthophosphate of potassa gives double phosphates which have different compositions; nor is there any isomorphism between thorine and zircon obtained by calcination of the double phosphates at very high temperatures.—On the ammonia present in the ground, by MM. Berthelot and André. In reply to M. Schlœsing's last paper the authors claim to have made good their original statement that the ammonia present in the ground should be analysed without any dessication or previous treatment. They also join issue on various incidental points raised by M. Schlœsing himself during the controversy.—On the extension to a class of analogous forms of the theorem relative to a number of asyzygetic invariants of a given type, by Prof. Sylvester.—On the discovery of a new metal, austrium, announced by M. Ed. Linnemann in the *Monatshefte für Chemie* for April 1886, by M. Lecoq de Boisbaudran. From the description given of its chemical properties, its electric spectrum, and the process of its extraction from the orthite of Arendal, the author thinks that this substance is very probably gallium, a small quantity of which might easily be contained in orthite. The two rays of austrium approximately measured by M Linnemann are $\lambda = 403{\cdot}0$ and $416{\cdot}5$, those of gallium being $403{\cdot}2$ and $417{\cdot}05$. For both the ray 417 is the strongest.—Remarks accompanying the presentation of three volumes of the *Annales du Bureau central météorologique* for 1884, by M. Mascart. Attention is drawn especially to M. Fron's paper on the distribution of thunderstorms in France during the year 1883; to M. Moureaux' memoirs on the methods employed at the Parc Saint Maur Observatory for the study of terrestrial magnetism; and to M. Teisserenc de Bort's paper on the distribution of cloudiness over the surface of the globe.—Observations of Brooks's Comet III. (c, 1886), made at the Observatory of Algiers (0·50m. telescope), by M. Ch. Trépied.—Developments in trigonometrical series of certain functions verifying the equation of the potential $\Delta F = 0$, by M. Appell.—Note on some new groups of surfaces of two dimensions in spaces of n-dimensions, by M. Giovanni Bordiga.—Observations on M. Ledieu's note relative to the roll of vessels at sea, by M. de Bussy.—On the vapours emitted by a mixture of volatile substances, by M. P. Duhem. It is shown that the partial pressure of the vapour emitted by each of the two fluids mixed together is less than the tension of saturated vapour of the same fluid taken in the pure state.—Dynamics of the molecule of water: velocity of the propagation of sound; compressibility; heat of fusion of ice; specific heat of ice, by M. M. Langlois.—Calorimetric study of iron at high temperatures, by M. Pionchon. A detailed exami-

nation is made of the characteristic modifications experienced by iron at a temperature of about 700° through the extremely rapid absorption of heat in a comparatively slight interval of temperatures.—Conditions under which is realised the maximum of useful work in an electric distribution, by M. Vaschy.—Note on atmospheric refraction, by MM. J. Chappuis and Ch. Rivière. This phenomenon is here studied by a method based on the employment of Jamin's interferential refractometer.—New facts bearing on the phenomenon of the apparent oscillation of the stars, by M. Aug. Charpentier. Several observations are made, tending to show that the phenomenon is of a purely subjective character, due especially to the unequal fatigue of the muscles of the eye, or rather to their innervation.—On the presence of a new element in samarskite, by Mr. W. Crookes. The already described abnormal orange band $\lambda = 609 = \frac{1}{\lambda^2}2693$, which the author supposed due to a mixture of the two earths yttrium and samarium, he now finds cannot be due to either of these, the only probable alternative being that it belongs to some new element. Until it can be separated from the asssociated substances and its chief properties determined, he proposes to name it Sα, the initial letter S indicating its samarskite origin.—On the dissociation of the hydrates of the sulphate of copper, by M. H. Lescœur.—Action of the acids and bases on emetic solutions, by M. Guntz.—Action of water and of ammonia on the chloride of methylene, by M. G. André.—Some new properties of cyanated camphor, by M. Alb. Haller.—A contribution to the study of the alkaloids, by M. Œchsner de Coninck. The author applies the method of MM. Hoogewerf and Van Dorp to the treatment of some iodides of pyridic ammonium—isomethylate of pyridine, C_5H_5N,CH_3I, and iodethylate of pyridine, C_5H_5N,C_2H_5I.—On the normal dinitriles

$$CN-(CH_2)_n-CN,$$

by M. L. Henry.—Chemical researches on the products of the eruption of Mount Etna during the months of May and June 1886, by M. L. Ricciardi. The sands collected at Cibali were of a blackish colour, consisting mostly of amorphous detritus mixed with crystalline fragments of labradorite, olivine, and pyroxene readily affected by the magnet. The ashes ejected on May 28–29 present similar characteristics with a larger quantity of salts soluble in water.—Volumetric analysis of the sulphur in the sulphides decomposable by hydrochloric or sulphuric acid, by M. Fr. Weil.—Researches on the growth of beetroot, by M. Aimé Girard. This paper deals especially with the stalk, which during growth consists of a tissue, in the elementary organs of which water and sugar, forming a constant quantity, are mutually replaced according to the circumstances.—Researches on the structure of the scorpion's brain, by M. G. Saint-Remy.—On the structure of the germ vesicle in *Siphonostoma diplochætos*, Otto, by M. Et. Jourdan.—On the post embryonic evolution of the vitelline sac in birds, by MM. Charbonnel Salle and Phisalix.—On the vascular system of *Spatangus purpureus*, by M. H. Prouho.—On the glands of insects: a pretended "new type of elastic tissue," by M. J. Gazagnaire. The paper deals especially with the unicellular glands first described by Meckel in 1846, and afterwards studied by Stein, Sirodot, Leydig, and others. To these are referable M. H. Viallanes' pretended "elastic cellules."—On some histological peculiarities of the digestive tube in the simple Ascidians, and especially the Cynthiæ, by M. L. Roule.—On the geological constitution of the Pyrenees: the Triassic system, by M. E. Jacquot. The author's investigations lead to the conclusion that along the French slope, from the banks of the Nive to the Teck valley, the Triassic formation presents a uniform composition, recalling that of the ranges in Franche-Comté, Provence, and Lorraine.

Berlin

Physical Society, May 21.—Dr. König spoke on the modern attempts towards laying down an unexceptionable basis of mechanics. Among the axioms of mechanics the law of inertia set up by Newton was the most important, but neither the conceptions of time, which lay at the basis of the idea of uniformity, nor the conception of the straight line, were precisely definable without further assumptions. A whole series of attempts had been made to fix these fundamental conceptions, attempts which the speaker briefly sketched. He came to the conclusion that as standard of time not the movement of translation, which could never be absolutely measured, but the movement of rotation must be recognised. The movement of rotation was perceptible in itself, namely, through the oblateness of the rotating ball. With regard to the straight line, that is with regard to our co-ordinate system in space, the speaker accepted the ideas set forth last year by Herr Lange of Leipzig, who started with a notion developed by Prof. James Thomson of Glasgow. Dr. König gave a graphic representation of the idea which had been only mathematically developed and established. According to this representation it was possible, when three points described in a particular space any paths whatsoever, to follow with a co-ordinate system these movements in such a manner that all three points moved rectilinearly. Experience taught that when three points described straight lines to such a co-ordinate system, each fourth, fifth, and so on, did it as well. Thus in the movements of rotation, and in the mobile co-ordinate system, unexceptionable bases of mechanics might be found whereupon to raise a superstructure, just as mathematics was built up on its axioms.

THE ETIOLOGY OF SCARLET FEVER

A REPORT has just been issued by the Medical Officer of the Local Government Board, the importance of which, as regards the etiology and prevention of a widespread infectious disease, deserves the most careful attention of sanitary officers and the general public alike. Hitherto the general assumption prevailed that infection with scarlet fever has always had its origin from the human subject, that is to say, that scarlet fever is always transmitted to the human subject from a human being affected with the malady, either by direct contagion in its wider sense, or through milk, cream, &c., previously contaminated with the contagium derived from a human source. In the present Report we have an account of an extensive outbreak of scarlet fever in the north of London at the end of last and the beginning of the present year amongst the consumers of milk derived from a particular farm at Hendon. The first part of the Report of the Medical Officer contains an account by Mr. W. H. Power, Inspector to the Medical Department of the Local Government Board, of an investigation into this outbreak, and the evidence brought forward by Mr. Power is absolute and conclusive: it proves by a chain of circumstantial evidence as complete as can be wished, that this particular outbreak of scarlatina was transmitted by milk which could not have been previously contaminated from a human source.

Moreover, Mr. Power proves that certain milch cows recently added to the dairy and affected with a particular malady were the source from which the contagium had been derived; further, that as this malady once introduced by a few cows into the dairy spread to other milch cows, so the amount of milk containing the contagium, and also the number of cases of scarlatina amongst the consumers, increased, and as the milk-supply was discontinued so the spread of scarlet fever abated.

The malady with which the cows were affected consisted chiefly in a particular kind of ulceration of the teats and udder, and perhaps some slight cutaneous disorder. As regards the general health, the feeding and milking capacity, the cows seemed to present very little alteration.

The second part of the Report contains an account, by Dr. Klein, of the minute pathology and etiology of this cow disease. In the first place, Dr. Klein ascertained that the local disease on the teats and udder is inoculable in its specific characters into healthy calves; secondly, that the cows affected with the local disease of the udder and teats were at the same time affected with a disease of the viscera, as proved by the *post-mortem* examination, in many respects similar to a mild form of scarlet fever in the human subject.

From the ulcers of the cow Dr. Klein isolated by cultivation a streptococcus or chain-micrococcus, possessed of distinct and special characters, both as to morphology and mode of growth in various nutritive media, particularly in milk: in this latter it grows in a peculiar manner, and very luxuriantly. With artificial cultures of this streptococcus a disease was produced in calves by subcutaneous inoculation which bears a striking resemblance to scarlet fever in man. The conclusion is thus forced on us that this streptococcus is identical with the materies morbi; further, that the scarlatina produced in the human subject by the consumption of milk from the Hendon farm was an experiment, carried out on a large scale, of infection with a cultivation in milk of the above streptococcus; and lastly, that the milk of the cows affected with the specific ulcers of the teats and udders became charged with the contagium by the hands of the milker during the act of milking. Although there are many details still wanting to complete the research, particularly those regarding the transmissibility of scarlatina from the human subject to the cow, there is sufficient evidence at hand already to warrant the hope that by a proper and effectual mode of superintending milk-farms it will be possible to considerably limit this dire scourge. A suggestion that at once presents itself is this: granted that the above-mentioned streptococcus is the real cause of the malady, there is no reason to doubt that boiling the milk would effectually destroy its life and infective power, just as is the case with all micrococci. True, the danger to contract scarlatina would hereby not be altogether annihilated, since cream cannot thus be disinfected, and since scarlet fever can unquestionably be contracted from a human source, but it must be obvious from this conclusive Report that milk *per se* coming from an infected cow plays a considerable *rôle* in conveying scarlatina from the cow to the human subject.

OILS AND VARNISHES

Oils, Resins, and Varnishes. Edited by James Cameron, F.I.C. (London: J. and A. Churchill, 1886)

THIS work, according to the preface, is intended to be "a hand-book useful to all interested in oils and varnishes, and especially to analysts, pharmacists, manufacturers, and technological students." The editor further states that in preparing this volume he used the information in Cooley's "Cyclopædia," which he has "supplemented from the latest publications." The modern literature of oils and varnishes exists chiefly in the form of workshop recipes, in trade journals, technological dictionaries and pharmaceutical publications, and if anybody ever wanted to know anything about the useful and heterogeneous products comprised under these terms he not unfrequently found it necessary to waste a good deal of time in hunting up the required information. This last addition to Messrs. Churchill's Technological Hand-books will therefore be valuable to those engaged in several distinct branches of industry, and the editor has certainly displayed considerable judgment in the selection and arrangement of the scattered materials which he has brought together in this little volume of some 370 pages in length.

Chemically speaking the word "oil" has no precise meaning. It seems in fact that an oil may be anything that is not water, since we have oils among such distinct families of organic compounds as the alcohols, acids, aldehydes, hydrocarbons, &c. Thus in Chapter I., on the "Chemistry of Oils," these compounds are in the first place classed under the usual heads of "fixed" and "volatile." Animal and vegetable fixed oils being generally ethereal salts of glycerol and acids of the fatty and

oleic series, we have in this chapter brief descriptions of glycerol (nitroglycerol and dynamite), the fatty acids from butyric upwards, and the acrylic series from oleic acid upwards. The descriptions of the acids are concisely given, and their occurrence, preparation, and physical properties briefly described. Of the chemistry of the higher homologues of the acids of these series but little is known, and the name of the acid which heads each paragraph is simply followed by its empirical formula This treatment is all that is necessary in such a work as the present, but it will certainly occur to the more advanced chemical readers that a very wide field of investigation is offered to those who interest themselves with the question of isomerism among these complicated compounds. Considering the cheapness and abundance of the commoner animal and vegetable oils in daily use it does appear somewhat remarkable that more work has not been bestowed upon them by scientific chemists, and that the information which we have concerning them should be almost confined to their commercial testing and valuation.

Animal oils, fixed and volatile, are described in the second chapter, the former being divided into animal oils proper (butter-fat, lard, neat's foot, tallow, &c.), fish oils (cod-liver, seal, sperm, whale, &c.), and insect oils (niin, ant-grease, &c.). Among the volatile oils of this class we have bone-oil, castoreum, and civet oils (animal), and ambergris (fish). The third and fourth chapters are devoted to vegetable oils, a list of 19 drying and 23 non-drying oils being given. Linseed and olive oils, the most important members of this group, naturally claim the largest amount of space, and the technology of these products is well treated of. The volatile vegetable oils are very fully dealt with, no less than 56 pages being devoted to their consideration. After a description of the various methods of extraction by distillation, solvents, &c., the oils themselves are described individually according to their vegetable sources, the botanical names of the class and order being followed by a descriptive list of the oils obtained from each group of plants. Thus under *Aurantiaceæ* we have the oils of bergamot, cedrat, citron, lemons, limes, neroli, and orange ; under *Caryophyllaceæ*, cajeput and clove oils, and so forth.

In the fifth chapter, empyreumatic, medicated, mixed, and perfumery oils are treated of. We give a specimen of the editor's conscientiousness in his description of medicated oils:—"EARTHWORM OIL. *Syn. Oleum lumbricorum* (E. Ph. 1744). Washed earthworms, ½ lb. ; olive oil 1½ pint ; white wine, ½ pint. Boil gently till the wine is consumed, and press and strain." We are not informed what special merit is possessed by this gruesome concoction, but it was no doubt applied in good faith in the last century. Under "mixed oils" will be found a collection of strange mixtures, some of which might have formed ingredients in that "charm of powerful trouble" brewed by the witches in Macbeth. The familiar "nine oils" of the past generation of housewives, and even furniture oil, find place herein, together with some three dozen others. Chapter VI. contains an account of waxes, which are classed as animal, vegetable, and artificial, a useful method of distinguishing these substances by their behaviour with chloroform concluding the section.

The seventh chapter, a somewhat lengthy one, is devoted to mineral oils, viz. those obtained by the distillation of shales, coal, lignite, and peat, and those found naturally formed in various parts of the world. The treatment of coal-tar and the petroleum industries are well described, and the chapter concludes with sections on the storage of petroleum and the construction of petroleum lamps. Oil refining is treated of in the eighth chapter, which is a short one—almost too short considering the large number of processes which are now or have been formerly in use. The methods for refining tallow, wax, petroleum, and resin oil are included in this chapter, besides the purification and bleaching of animal and vegetable oils proper.

The longest chapter in the book is the ninth, which extends to 109 pages, and is devoted to the important subject of the testing of oils. This chapter is certainly a good one, both for thoroughness and the arrangement of its contents. Thus the testing of an oil may have for its object, the determination of purity, the lubricating efficiency, or the illuminating value. The purity may be ascertained by chemical or physical tests, both of which methods are very fully and lucidly treated of for each class of oils. Among physical tests are described the various methods of determining the specific gravity and melting point, cohesion figures, &c. The descriptions of the latter, which are quoted from a paper by Miss Crane, would have been of more value if figures had been given. The chemical tests, qualitative and quantitative, are given with great completeness. A figure of Abel's petroleum tester and the method of using it as prescribed by the Act of Parliament finds place in this section. For testing the lubricating value the machines of Stapfer, Thurston, and Bailey are described and figured ; for viscosity the apparatus devised by Lamansky, and by Townson and Mercer ; and for fluidity the apparatus of Bailey is also described and figured. The section on illuminating efficiency is not so full, and might be advantageously expanded in a future edition.

Chapter X. is devoted to resins and varnishes, and the last chapter contains descriptions of Mills' bromine absorption process and Hirscholm's method of testing resins. The appendix contains some useful tables of prices, of the amount and value of the export of seed oils during 1882, 1883, and 1884, and of the production of shale oil in the United Kingdom during the last five years.

From the foregoing epitome of the contents it will be seen that the volume, although a small one, gives a most comprehensive view of the subject of which it treats, and the amount of useful information which has been condensed into this small compass is mainly due to the concise mode of treatment which the editor has adopted. We can certainly recommend it to those for whom it is written.

R. MELDOLA

HARTLAUB ON THE MANATEES

Beiträge zur Kenntniss der Manatus-Arten. Von Dr. Clemens Hartlaub (Bremen). Separatabdruck a.d. *Zoologischen Jahrbüchern*, Band I. (1886.)

AMONGST other interesting articles with which Dr. Spengel's new zoological journal has commenced its career is one by Dr. Clemens Hartlaub (son of the

veteran ornithologist of the same name) which deserves special attention, as devoted to a somewhat neglected and imperfectly known group of the class of mammals—the Manatees or "sea-cows," as they are popularly called. The Manatees constitute, as is well known, one of the three modern representatives of the formerly more extensive order of Sirenians, or "Herbivorous Cetaceans," as they are sometimes, though not very correctly, denominated; for it is doubtful whether they have any near relationship to the true Whales. One of these three forms—the *Rhytina stelleri*—is already extinct; the other two—the Manatee and Dugong—are rapidly diminishing in numbers before the advancing tide of civilisation, and it is highly desirable that full details of their structure and habits should be obtained and recorded before they are "improved" off the face of the earth.

Dr. Hartlaub, having examined the skulls and other specimens of Manatees preserved in the various museums of the Continent, presents us with a *résumé* of his investigations in two well-ordered and well-illustrated essays. In the first of these he describes the skull of the African Manatee (*Manatus senegalensis*), and compares it bone by bone with that of the American *M. latirostris*, fully establishing the specific difference of the two forms, which has been doubted even by some of our most recent and best authorities.[1] In the second memoir he describes for the first time the skull of the South American *Manatus inunguis*, a species absolutely ignored by the great majority of naturalists, and shows its distinctness from *M. latirostris*.

It is hardly necessary even to recapitulate the points of difference between these three forms of Manatees, which Dr. Hartlaub has given at full length in these memoirs, and which seem to be sufficiently obvious on reference to his well-drawn figures. But a few words may be added on the geographical distribution of the three living Manatees, so far as this is at present known to us.

The African Manatee inhabits the west coast of that continent from the Senegal down to the Quanza, and penetrates up the larger rivers far into the interior. In the Senegal it has been recorded by Adanson, in the rivers of Liberia by Büttikofer, in the Niger and Benuë by Barth and Vogel, in Gaboon by Du Chaillu, in the Lower Congo by Johnston and Pechnel-Loesche, and in the Quanza by Monteiro. Whether the "*Charuf el bachr*," or water-sheep, ascertained to exist in the Uelle by Schweinfurth, which is probably the same as the supposed Manatee found in the Shari and Lake Tchad by Barth and other travellers, should be referred to *Manatus senegalensis*, or is even a Manatee at all, remains an interesting subject for future inquiry. But it seems tolerably certain that some sort of Sirenian inhabits the inland basin of Lake Tchad, and the probability is that it will turn out to be a *Manatus*.

In America the exact boundaries of the two species, *Manatus latirostris* and *M. inunguis*, cannot yet certainly be stated, owing to the confusion that has hitherto existed between these two forms. But it is certain that the Manatee occurs on the Atlantic coast of America from 25° N.L. to 19° S.L., and that those of the Antilles, the Gulf of Mexico, and Surinam, are referable to *M. latirostris*. On the other hand, *M. inunguis* is only certainly known from the Amazons and its tributaries, where it was first discovered by Natterer. Dr. Hartlaub is inclined to believe that the Manatee of the coast and rivers of South-East Brazil must be likewise *M. inunguis*, but this does not seem to be probable. It is more likely, we think, to turn out that one species is found all along the Atlantic sea-board, penetrating only slightly up the rivers, while the other is confined to the interior, and is a purely fresh-water species.

OUR BOOK SHELF

Infant-School Management. By Sarah J. Hale. (London: Stanford, 1886.)

THIS is one of the best books on infant-school management that we have seen; the authoress knows exactly the kind of information infants can most readily assimilate, and how best to impart it; while on the other hand she is fully aware how dangerous and worse than useless the forcing process is.

The second part of the book consists of sketches of lessons in natural history, natural phenomena, food-plants, and common objects; and if science is to be taught in all our infant schools in the manner our authoress suggests, we may look forward to a largely increased taste for science in the rising generation.

Here is an extract from the introduction to the second part showing the method of teaching which she recommends:—

"In every case the teacher must bring plenty of illustration to bear upon the lesson. In natural history *the real animal* or a good picture, and if possible, some thing or things that it furnishes us with, as, for instance, the fur of the otter, the shell of the tortoise, the quills of the porcupine. Also the teacher should carefully provide herself with pictures of animals which afford strong contrasts to the one with which she is dealing, as well as those which bear some general resemblance to it, that she may exercise the *discriminative* as well as the *assimilative* faculty of her pupils. In all object lessons, various specimens of the object should be produced for examination and description; the little ones themselves must do the main part of the latter under the teacher's guidance, for these lessons are not only to enable the children to form new ideas, but they are also intended to train them in giving expression to such ideas. The teacher must make good use of the black-board, and should practise drawing objects, so that she may illustrate with facility and precision any particular point of her lesson which can be so illustrated. All the materials, pictures, diagrams, &c., which the teacher provides from time to time, should have their place in the school museum ready for future needs, and the children should be encouraged to bring contributions to such a museum, particularly such as the lessons they receive may suggest. Object-lesson cards, pictures, and all illustrations should be carefully used, and when not in use, have their proper places on wall or shelf. The teacher should arrange all specimens in the museum, and have each addition neatly labelled and catalogued."

A Year in Brazil. By Hastings Charles Dent, C.E., F.L.S., F.R.G.S. With 10 Full-page Illustrations and 2 Maps. (London: Kegan Paul, Trench, and Co., 1886.)

THIS is a very interesting account of a year's sojourn in an interesting country, and although the author went out for a special purpose, to survey for a railway, every moment of his spare time was taken up in making collections and taking notes in most of the branches of natural history. The scientific interest of the book is mainly

confined to the notes on animals, birds, reptiles, insects, and the parasitic torments of Brazil, notes on botany and on geology, together with a discussion of the theory of evolution and observations made on protective colouring and mimicry.

With reference to the theory of evolution the author states that he has constantly endeavoured to oppose it, on the ground apparently put forward by theologians many years ago before they knew what the theory really was; and we think that if our author will continue his scientific studies a little longer he will probably find that the arguments he uses against it are really not in point.

The Colloquial Faculty for Languages. By Walter Hayle Walshe, M.D. Second Edition. (London: Churchill, 1886.)

THIS is a book full of pleasant gossip round the central idea embodied in its title; hence we have essays on the nature of genius, the conditions regulating colloquial faculty, and the causes of variety of colloquial faculty and faculty for translation.

In the chapter on composition in foreign tongues it is pointed out that the man of science proves now and then well capable of wrestling effectively with the humorist on his own ground of the *literæ humaniores*, and gives as an example Herbert Spencer's *exposé* of abounding errors in a passage from Addison quoted by Matthew Arnold, as an example of classical English.

We gather from our author that the English race is not the most gifted with the colloquial faculty, and a remark of Prince Bismarck's is quoted that he had always found that an Englishman who could speak good French was a doubtful character.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Periodicity of Glacial Epochs

PERMIT me to ask, as a matter of international comity in science, the help of my learned British colleagues in the following matter.

I am just now occupied upon a work treating upon the periodicity of glacial epochs, a question which has already been broached by me in previous writings several years ago. The cause of this phenomenon being attributed by the astronomers, as well as by the majority of geologists, to the displacement of the perihelion, whose cycle is 21,000 years, it follows that, according to the actual position of this point, the ice now covering the Antarctic regions had its maximum of intensity at about the year 1250 of our era. For the same reason, the ice of the boreal hemisphere must have offered at this same epoch its minimum of intensity. Consequently the latter must have been increasing since the close of the thirteenth century, while the former must have been receding. The researches of European geologists must have shown a marked extension of the glaciers of Spitzbergen, Greenland, &c., since the beginning of the fourteenth century, and a recession of vegetation from the latitude of Sicily to the Polar Circle. But we in France are not informed of what has happened in the southern hemisphere since the arrival of the first navigators. I would therefore, in the name of science, beg of any British officers, consuls, or scientific observers who are, or may have been, collecting facts at stations near the South Pole, in Patagonia, New Zealand, Tasmania, and elsewhere, to communicate to me directly, or through your columns any information they may have upon this subject. I wish to know whether, since the first arrival of Europeans in those regions, the ice field has shown a recessive movement, accompanied by an inverse tendency of vegetation.

Evidence of Man and Pleistocene Animals in North Wales prior to Glacial Deposits

SOME of the results recently obtained during the researches carried on at the Tremeirchion caves under the superintendence of Mr. E. Bouverie Luxmoore and myself, seem to me of so much importance that I have thought it advisable to communicate them, in anticipation of the full report which will be presented to the British Association, especially as an important section is now exposed, and may be examined by any one desiring to do so, which will probably have to be covered before the end of the summer.[1]

In continuing our explorations this year, by means of a grant from the British Association, we found that the Cae Gwyn Cave (described in my paper in the *Quart. Journ. Geolog. Soc.* for February last) had come to an abrupt termination in a plateau of Glacial deposits. On further examination it was found that this must have been the main entrance into the cavern when it was occupied by the Pleistocene animals, and that the Glacial beds in and upon it must have been deposited subsequent to the occupation by the animals. As in the other parts of the cavern, the cave-earth at the entrance—a brown sandy clay, contained fragments of a stalagmite floor and of stalactites along with angular fragments of limestone. The bones also occurred at all angles, showing that the contents had been greatly disturbed by water action. The bone earth was covered over at the entrance and for some distance inwards by a few feet of stratified sand, containing well-scratched boulders, and it, as well as the sand, was traced for a distance of fully 6 feet beyond the entrance under the series of Glacial deposits, shown in the section.

In digging outside the entrance, the floor of which is 20 feet below the surface of the field, it was soon found that we could not extend our researches outwards, owing to the nature of the lower deposits, chiefly sands and gravels, without making an opening into the field. By the kindness of the owner, Mr. Edwin Morgan, a shaft was allowed to be dug in front of the opening, about 9 feet across at the surface and over 5 feet at the bottom. This shaft was subsequently widened at the bottom, in consequence of some falls, and the lower part, except at one point, had to be carefully faced with timber. The upper part of the shaft is now much widened and sloped. To make it certain that the Glacial deposits are continuous from the shaft in a westerly direction, I had the beds probed at different points for a distance of about 70 feet; and subsequent examination showed clearly that there is here an extensive terrace of drift reaching to heights of between 400 and 500 feet above Ordnance datum. The section was carefully taken at two different points in the shaft by Mr. C. E. de Rance, F.G.S., of the Geological Survey, and myself, and in doing so we found well-scratched boulders in each of the deposits. Among the boulders found are granites, quartzites, flint, felstones, diorites, volcanic ash, Silurian rocks, and limestone. Silurian rocks are most abundant. It is clear that we have here some rocks from northern sources along with those from the Welsh hills, and the manner in which the limestone at the entrance to the cavern is smoothed from the north would indicate that to be the main direction of the flow. A small but well-worked flint flake was dug up from the bone earth on the south side of the entrance on June 28, in the presence of Mr. G. H. Morton, F.G.S., of Liverpool, and myself. Its position was about 18 inches below the lowest bed of sand. Several teeth of hyæna and reindeer, as well as fragments of bone, were found at the same place, and at other points in the shaft teeth of rhinoceros and a fragment of a mammoth's tooth. One rhinoceros tooth was found at the extreme point examined, about 6 feet beyond and directly in front of the entrance. It seems clear that the contents of the cavern must have been washed out by marine action during the great submergence in mid-Glacial time, and that they were afterwards covered by marine sands and by an upper boulder-clay, identical in character with that found at many points in the Vale of Clwyd, and in other places on the North Wales coast.

The facts obtained seem to me to prove conclusively that man and the Pleistocene animals must have lived in parts of the North Wales area, and have occupied some of the caverns, before the period of the great submergence indicated by the Moel Tryfaen and other high-level sands; hence certainly before the Upper Boulder-Clay was deposited. HENRY HICKS

[1] Tremeirchion is about four miles from St. Asaph, and less than two miles from Bodfari Station on the Chester Mold, and Denbigh line.

Ampère's Rule

BEGINNERS are certainly, as Herr Daehne says (NATURE, June 24, p. 168), liable to get a little "mixed" in reference to the above *mem. technica;* chiefly, I think, for want of some idea sufficiently prominent to fix itself on the mind to the exclusion of others.

I have found the following slight modification of the original rule pretty easily remembered and applied.

It may be taken as agreed—

(1) That the *head* is more important ("more worthy," as the old grammars put it) than the *feet*.

No one except an acephalous mollusk will deny this; and *it* is not a fair judge.

(2) That the *right* hand is more important than the left hand. The left-handed people are a mere minority (and a nuisance at cricket); and minorities are, according to modern Radical ideas, "une quantité négligeable."

3. That the N-seeking pole is that part of the compass-needle to which attention is mainly directed.

Now,—If a person places himself so as to face the needle, and a current goes from HEAD to foot, the N-SEEKING pole moves to his RIGHT hand.

This is practically the form in which the rule is given in Prof. Balfour Stewart's "Lessons in Physics." One of the small articulated wooden figures used as models in drawing is very useful for illustrating the above rule. Its right arm may be stretched out sideways at right angles to the body, and it may then be held close to the wire in various positions; paper arrows being tied to the latter, to mark direction of current.

Eton College H. G. MADAN

Halos

As the atmosphere appears recently to have reassumed in a marked degree some of the peculiar conditions which pertained to it during the time of the great sun glows, I have thought it worth while to send you notes from my diary of some effects observed by me:—

June 14.—Between 10 and 11 a.m. Complete solar halo of a coppery colour. It lasted more or less distinctly for some time, and gradually faded. I saw no trace of mock suns.

June 23.—Between 10 and 10.30 p.m. there was a curious pearly green light in the north-north-east, and some peculiar pearly green clouds (?) floated from north to west. At first I thought this was an auroral display, but probably it was due to the same cause as the "glows."

June 15, 23, 30, July 1, 2, and 3.—After-glows of the usual pinkish hue. J. H. A. JENNER

The Microscope as a Refractometer

I HAD no idea that the short paper you did me the honour to print on this subject would have led any one to suppose that a claim was made for the discovery of a new principle in physics, or that the microscope was to be used for the first time in questions on refraction.

In so short a space it was impossible to tell over again the tale of progress in this branch of physical optics, and to signalise every worker in the field by name. So much has already been done in the perfecting of optical instruments, that the utmost one can now hope to do is, by a slight improvement here and there, to render them still more serviceable.

All that was claimed as new in my paper of June 17 was—

(α) The use of the marked slip, structure of cell, superposed cover-glass.

(β) The measurement of the linear distances between the images by a finely graduated "fine adjustment" screw.

(γ) The use of an objective of high amplifying power (a 1/20-inch homogeneous immersion may be used if the shoulder-pieces of the cell are made with talc, and the cover-glass very thin).

It is of course possible that one or all of these details is not new; but, in spite of the authorities quoted by Dr. Gladstone to show the previous employment of the microscope in questions of refraction, I still maintain their claims to novelty to be valid; and, even supposing they are not new (which has yet to be shown), my greatest offence is that of independently arriving at a previously known method. And, considering the attention that our most eminent physicists have bestowed upon the subject, the wonder is that this has not more frequently been the case.

As to the efficiency of the method, the only objections urged against it by Dr. Gladstone are: (1) its results cannot be relied upon beyond the third decimal figure; (2) the temperature of the drop of fluid under examination cannot be taken.

As to the first objection, if we take μ_1, μ_2 as the tabulated indexes of refraction of two known substances, δ as representing the difference of distance between the images of the marks viewed through them, and measured by the fine adjustment, μ and d the corresponding symbols for the fluid under examination, we have the following equation to determine μ:—

$$\frac{\mu_2 - \mu_1}{\mu - \mu_1} \times \frac{\mu}{\mu_2} = \frac{\delta}{d}.$$

And I see no more reason to limit the exactness of this to the third decimal figure than in the formula used with the hollow prism. Moreover, if a vernier is attached to the fine adjustment the result may be relied upon with still greater accuracy.

(2) As to the temperature. In the case of most fluids this may be taken from the bottle containing the fluid; no grave scientific error will arise from the difference in temperature of a drop of fluid in contact with glass on the stage of the microscope and the same fluid in a glass bottle by its side. In the case of ethers, &c., the cell may be temporarily sealed.

As to the practical use of the method, the opinion of so known an expert as Dr. Gladstone is of the greatest weight, but as any recognition of the novelty of my method escaped acknowledgment in his notice, I may still hope that its practical use escaped observation also. So thin a stratum of fluid is employed that the index of refraction of black ink may be obtained, a result which would puzzle any one to arrive at who restricted himself to the use of the hollow prism.

That the microscope has been previously used for experiments in refraction no one ever doubted; if Dr. Gladstone, before writing, had had the time to go step by step through my method, he could scarcely have refrained from acknowledging that in its essentials it was hitherto unpublished.

The Bagshot Beds

As you have given publication (NATURE, July 1, p. 210) to the abstract of the paper recently read by Messrs. Monckton and Herries before the Geological Society, in which they assert that their object was to "disprove" the view lately propounded by me, as to the relation of the Bagshot Beds of the London Basin to the London Clay, perhaps you will kindly afford me space to point out to the readers of NATURE (1) that these authors have ignored, in dealing with the question, whole chapters of the evidence upon which my view is based—evidence which is continually accumulating, as two forthcoming papers (one in the press for the *Proc.* Geol. Assoc., the other in the hands of the editor of the *Geol. Mag.*) will make manifest enough; (2) that in directing their attention merely to sections at the outcrop of the beds they have added little, if anything, substantially, to that on which the old view was based, while the lithological distinctions of the Upper and Lower Bagshot Beds (where the latter have been for ages undergoing oxidation) are not sufficiently marked to furnish, in disconnected sections, evidence which can be anything more than, to say the least, equivocal. Wellington College, Berks, July 3

The Enemies of the Frog

IN connection with this subject the following incident may be of interest to some of your readers. One day, near the kitchen area, an unusual noise was heard: it seemed like the mewing of a cat combined with a well-sustained whistle. On going to the spot, it was found that the noise proceeded from a cat and a frog, but it was difficult to decide from *which* of the two. Every time the cat touched the frog the sound was produced and the frog hopped away. The cat exhibited in his attitudes and motions a sort of enjoyment mingled with awe. He would just touch the frog very gently with the tips of his paws, then watch it most attentively, and when the frog would emit its peculiar loud squeak—not the usual croak—he would give a sudden bound, as if both surprised and amused; but he never

attempted during the whole of the proceedings, which lasted about a quarter of an hour, to bite the frog. The frog was removed quite uninjured, but apparently exhausted either by fear or by muscular exertion.

Hybrids between the Black Grouse and the Pheasant

IN Yarrell's "British Birds," 4th ed. vol. iii. p. 69 *seq.*, a number of hybrids between the cock pheasant and the gray hen are enumerated as having occurred in England. Being desirous to give a life-sized and coloured figure of such a hybrid in my forthcoming work on the black grouse, the capercailzie, and their allies, I wish to borrow a specimen for a short time, and, as my endeavours to procure one have so far been unsuccessful, I beg to make this known through your widely read journal, hoping that some fortunate possessor may be kind enough to communicate with me concerning his willingness to lend me a specimen for the said purpose.

THE FINSBURY TECHNICAL COLLEGE CONVERSAZIONE

THE annual *conversazione* given by the students of the above College as the closing event of the session came off on Friday evening, July 2, and proved in every way a success. The large number of interesting objects brought together for exhibition certainly speaks well for the activity of the various committees which were intrusted with the work of organisation, and at the same time indicates how widely spread is the interest shown in the welfare of the College by the different firms of manufacturers who contributed to the exhibition. The electrical department exhibited in action most of the apparatus used for educational purposes in the College. In this department also were exhibits of apparatus and models by Messrs. Woodhouse and Rawson, the Electric Apparatus Company, Messrs. Mayfield's vacuum-tubes, and other electrical and physical apparatus made by this firm. The exhibits in the chemical department were especially numerous and representative of chemical technology in most of its branches. In the way of apparatus Messrs. Cetti, of Brooke Street, exhibited barometers, thermometers, vacuum-tubes, &c.; Messrs. Townson and Mercer showed a new carbonic acid generator, Schutzenberger's gas apparatus, filter pumps, nickel crucibles and basins, Pasteur flasks, inland revenue stills, Abel's petroleum testing apparatus, &c.; and Mr. B. Redwood lent a set of viscometers. Fine chemicals were exhibited by Messrs. Hopkin and Williams, and a splendid set of alkaloids and other products by Messrs. Howard of Stratford. Messrs. Pontifex and Wood exhibited sets of pigments and the materials used in their manufacture, Mr. C. Richardson a set of specimens illustrating the manufacture of cements, Mr. Ashley samples of English and foreign lubricating oils, and Messrs. J. and L. Cripps the materials and finished products representing the manufacture of size, glue, and gelatine. Glass manufacture was represented by a set of tools and specimens from the Whitefriars glass-works (Messrs. Powell). Messrs. Field showed a fine series of waxes and other materials used in candle-making, and a good exhibition was made also by Price's Patent Candle Company. The manufacture of soap was illustrated by a very complete set of specimens contributed from Messrs. E. Rider Cook's works at Bow and by Messrs. Knight, &c. Cotton seed and its products were shown by Messrs. W. and W. H. Stead of Blackwall and Liverpool. The specimens and diagrams sent by Gaskell, Deacon, and Co., of Widnes, gave an excellent idea of the alkali manufacture in this country.

The collection of coal-tar products was especially rich, specimens having been sent by the Badische Company, the Hoechst Colour Works, Messrs. Brooke, Simpson, and Spiller, the British Alizarine Company, and Messrs. Burt, Boulton, and Haywood. The latter firm exhibited a splendid model of their timber creosoting plant. Amongst other tar products was a set of preparations of the new sweetening substance, saccharine, sent by Dr. Fahlberg. The Broadburn Oil Company showed a very complete set of shale products. The sugar industry was represented by a set of polarimeters, models and specimens, exhibited by Mr. Newlands of the Clyde Wharf Sugar Refinery, and by the Beetroot Sugar Association. In the course of the evening Prof. S. P. Thompson gave a lecture on waves of light, and Mr. John Castell-Evans discoursed on explosives. The entertainment was on the whole highly creditable to the College, and many of the firms who sent objects for exhibition have signified their approval by presenting their exhibits to the establishment as lecture specimens.

THE RECENT DISCOVERIES AT TIRYNS[1]

THE excavations made during the last two years at Tiryns, by Dr. Schliemann and Dr. Dörpfeld, have thrown new light on what has been hitherto an almost unknown period of Greek history—that far-off time, more remote even than the age of the Homeric poems, when Hellenic civilisation had not yet emerged from its Oriental cradle, nor developed its highly cultured systems of social and political government out of the splendid but semi-barbarous tyrannies of Western Asia Minor.

The literature of Greece has made us familiar with the later times, when the individual was for the most part merged in the State, and when the wealth and artistic skill of each city was devoted to public uses, such as the Council-chamber, the Agora, or the stately temples of the gods, rather than to the luxury of any one person.

But at Tiryns a very different picture is presented to us: we see a single autocratic chieftain, ruling in a sort of feudal state, and occupying a magnificent palace, surrounded by the humbler dwellings of his circle of retainers; while, instead of the utmost resources of the architect, the sculptor, and the painter being lavished on the shrine of the presiding deity, a mere open-air altar is dedicated to the god, and it is the chieftain's house which is decked out with the splendours of gilt bronze, marble sculpture, and painted walls.

The rock in the marshy plains of Argolis, on which stands the citadel of Tiryns, is about three miles distant from the Gulf of Nauplia, and commands an extensive view reaching from Argos, with its rich olive-groves, to Mycenæ on its lofty crags, and, between the two, the once prosperous sea-port of Nauplia, by the blue waters of its sheltered bay.

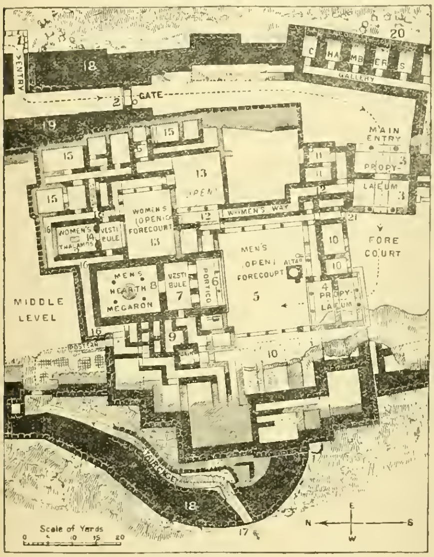
The massive fortification wall which surrounds the Tirynthian Rock was an object of wonder and admiration in the earliest historic times of Greece: its enormous stones keenly aroused the Greek imagination, and created legends which attributed them to mysterious Cyclopean builders, and peopled the walls with the demi-gods of the heroic age, such as Perseus and Heracles, whose early youth was fabled to have been spent in the Tirynthian city—the Τίρυνς τειχιόεσσα of Homer's "Iliad." This wonderful wall, some stones of which are no less than 11 feet long and 4 feet thick, was originally nearly 50 feet high at its loftiest part, measuring from its base outside: inside the city the height was very much less, as its lower part acted as a retaining wall, which kept up the loose earth which formed a level interior surface above the irregular contour of the rock.

The southern part of the Acropolis wall, where it incloses the great palace, is a very complicated structure,

[1] "The Prehistoric Palace of the Kings of Tiryns." The results of the latest excavations, by Dr. Henry Schliemann. The preface by Prof. F. Adler, and contributions by Dr. Wm. Dörpfeld. With 188 woodcuts, 24 plates in chromolithography, 1 map, and 4 Plans. (London: John Murray, 1886).

containing long rows of small vaulted chambers averaging about 14 feet by 12, all opening into a long vaulted passage, the whole formed in the thickness of the wall itself, which at some places consists of nearly 40 feet of masonry. Two stories of these chambers existed, one above the other: the lower story is of solid stone masonry, built of large hammer-dressed blocks, bedded in clay cement. The upper tier of chambers was built of sun-baked bricks, like the upper part of the wall round Athens, carefully protected from the weather by coatings of very hard durable stucco. This top story of rooms opened into a long open *loggia* or colonnade, with a flat roof supported by a range of wooden columns, each on a stone footing block.

The columns themselves are of course no longer in existence, but their size and positions are clearly shown



PLAN OF THE PALACE MEASURED BY DR. DÖRPFELD.

1, Main gate in outer wall; 2, inner gate; 3, main propylæum; 4, inner propylæum; 5, court of the men with surrounding cloister, 6, aithousa, or portico; 7, prodomos, or vestibule; 8, men's hall; 9, bath room and small chambers; 10, chambers round the court; 11, guard-room by the propylæum; 12, passage from propylæum to the women's part; 13, 13, courts of the women; 14, women's hall; 15, chambers of the women's part; 16, 16, passage from the women's part to the outer postern; 17, postern door, approached by rock-cut steps; 18, outer wall of Acropolis; 19, inner wall of entrance passage; 20, outer wall with rows of chambers; 21, side entrance to men's court.

by the stone base on which each stood. These extensive series of chambers in the wall of Tiryns served, no doubt, to accommodate the garrison of the place—exactly as was the case in the Phœnician cities of Thapsus and Carthage. The enormous number of 24,000 men are said to have had lodging in the walls of the Carthaginian Acropolis (Appianus of Alexandria, "Hist. Rom.," i. p. 220), and recent discoveries have shown that this statement may very possibly have been no exaggeration.

More than a third of the whole Acropolis of Tiryns was occupied by the palace of its ruler—a very complicated building designed with much architectural skill, and showing complete uniformity of design combined with very distinct adaptation to a clearly defined purpose.

With the exception of three very narrow posterns, there is only one entrance into the citadel; and this is very skilfully contrived so as to make its defence as easy as possible.

After breaking through the outer gate, which was commanded by a tower on the right or unshielded side of the enemy, the assailants would have found themselves in a narrow passage with massive walls on both sides, and strong inner gates at each end; and in this cramped space would be subjected to a heavy fire of missiles poured down upon them from all sides.

After passing the inner gate in a southern direction, a handsome propylæum or porch was reached: this was decorated on both sides by a portico of two columns *in antis*, and is very similar in plan to the propylæum of the sacred inclosure at Eleusis—a work of the fifth century B.C. (See the accompanying woodcut of the plan.)

After passing through an open court, a second propylæum of similar design was reached, and then the visitor found himself in the cloistered court of the men's part of the palace. In the central open space stands the altar to Zeus Herkeios, which is frequently named in the Homeric poems, built over a small pit cut in the rock, into which would fall the blood and ashes from the burnt offering on the altar above. Opposite the entrance to the court is the great hall or Megaron (about 40 feet by 32), approached through an open-columned portico and an inner vestibule. The roof of the hall was partly supported on four wooden columns, which appear to have carried an open "lantern," formed to carry off the smoke from the fire, which burnt on a round hearth in the middle of the room; very much as was the case in the hall of a mediæval house or college.

On the west side of the hall of the men are a number of small chambers—probably the sleeping-apartments of the bachelor members of the family. One small room, about 12 feet by 10, is of extraordinary interest. It is evidently a bath-room; its floor is formed of one enormous slab of stone, carefully chiselled so as to drain out at one point where a stone drain-pipe is carried through the wall, and so into the main drain of the house.

The bath itself, in size and form very like a modern one, was of terra-cotta decorated with a spiral ornament in red.

The walls of the bath-room were lined with wooden planks about 10 inches wide; their lower ends were fastened by wooden dowels to the stone flooring block, the edge of which all round the room is raised slightly where the wood wall-lining rested on it: evidently in order that water splashed on the stone floor might not soak under the wood lining: a piece of refinement which shows much thought and labour spent on matters of detail.

The eastern half of the palace consists of the apartments reserved for the women and the married members of the chief's family. This also has a hall with a central hearth, and is approached through a single vestibule from another open court. The smaller rooms, of which there are a great many, on this side appear to have been two stories high: traces of the staircase still exist.

Though a separate group of apartments appears to have been provided for the women, yet they were by no means shut off from ready access either to the outer world, or to the men's part of the house. There are at least three ways by which the women's rooms could be reached: one from the side of the outer propylæum, another through the court of the men, and lastly a long passage leads round the back of the men's hall to the long flight of rock-cut steps leading down to the postern in the semicircular bastion. Another door at a higher level gave direct communication between the hall of the men and the apartments of the women.

The walls of this palace were built of roughly-dressed stone bedded in clay up to a height of about 2 feet above

the ground: the rest of the wall was of sun-dried brick; the whole was then covered inside and out with three coats of stucco made of lime mixed with sand, gravel, and broken pottery, a mixture which set nearly as hard as stone, and must have been a most perfect protection even in the stormiest weather. Finally, where the stucco was to be painted a thin coat of pure lime was applied as a ground for the colours, which consisted of red, yellow, and brown ochres, with charcoal-black and lime-white; and lastly, blue and green *smalti* or pigments, made of powdered glass. All these colours were of the most durable sort, and could be applied, as appears to have been done at Tiryns, on freshly-laid stucco—true *fresco*.

The painted decorations are of the very highest interest, and very characteristic examples of primitive art, which show strong traces of Egyptian or Phœnician influence. Some of these wall-paintings are evidently copied from textile patterns, and, though rudely executed, have much true decorative value. Woven stuffs such as were made in Egypt are imitated by the painter, and even the fringes are carefully copied. Other pictures, of which only fragments remain, had large figures of animals or men with wide-spreading wings, the feathers of which are painted in alternating colours in a very brilliant and skilful way. These show strong signs of Phœnician influence. The most remarkable and best preserved of all is a picture of a bull galloping at full speed, on whose back a man is riding in an acrobatic sort of way, holding on by one of the bull's horns. The whole is painted with much vigour, and with a rapid sweeping touch of the brush, which shows considerable practice and skill on the part of the painter.

Some parts of the palace were evidently decorated in a much more magnificent and costly way—that is, the walls were lined with wooden boarding, and on this were nailed plates of gilt bronze beaten into *repoussé* reliefs—very similar probably in style to the ninth century gates of Shalmaneser II., now in the British Museum, and other bronze reliefs found at Olympia. Many small fragments of these gilt metal linings were found in the burnt debris of the palace; and there is little doubt that the wooden columns in the hall and its portico must once have been cased with similar metal sheathing: very like the bronze-cased wooden column which was found some years ago among the ruins of Khorsabad.

Nothing could exceed the splendour of this mode of wall-decoration—the whole surface enriched with its gleaming reliefs would appear one mass of shining gold, and we know now that the gold and silver walls of the Homeric palace of Alcinous were not merely the offspring of a poet's fancy. Fragments were discovered by Dr. Dorpfeld of another extremely sumptuous method of architectural decoration—a frieze about 20 inches deep sculptured in alabaster with a rich and minutely worked pattern of rosettes and geometrically treated flowers, thickly studded with carefully cut bits of jewel-like transparent blue paste or glass. The effect of these deep-blue jewels flashing light from the contrasting creamy white of the alabaster must have given a most striking effect to the room which was adorned in so costly a way, especially if the wall below the frieze were one of those which were coated with the gold reliefs.

Nor was the colour confined to the walls: even the floors were decorated with simple patterns in brilliant blue and red, applied after the design had been indicated by lines incised on the surface. These floors were made of strong lime and gravel concrete carefully laid in three or four layers, each of finer material than the one below—a method exactly similar to that described by Vitruvius and used so skilfully by the Roman builders.

A very interesting point about the Tirynthian palace is its very careful method of drainage, partly with neatly fitted clay drain-pipes, and partly with large culverts built of rough stone and puddled inside with clay: this latter form was used for the main drains, while the branches which led to it were of pipes square in section, each length of clay pipe being narrowed at one end so as to fit closely into the next. All the open courts were well paved with concrete, which was laid so as to fall to a surface-gully, down which the rain-water passed, first through a clay pipe, then into the main stone drain, and so into a series of cisterns, where it was stored for use during a siege.

Much manual skill and great variety of tools were used by the masons who worked the stones for this building. Pointed hammers were used for the rough work, and chisels for the ashlar stone: the large thresholds of the various doorways were cut with a saw, with which emery must have been used, as its marks show that each stroke of the saw cut a considerable depth into the stone. Hollow drills set with some kind of hard jewel were also used here: in many of the drill-holes used to fix the pegs or dowels of the wood-work above, the stone stump of the core still exists, showing that a tubular, and not a solid, drill was used. Some of the large quoins or angle blocks were quarried thus—four drill-holes were sunk at the four corners of the future block, and then saw-cuts were made from hole to hole.

This use of tubular jewelled drills, which has recently been introduced with such effect into modern methods of engineering, dates from a very early period. As Mr. Flinders Petrie has pointed out, jewelled drills, both solid and tubular, were used in Egypt as early as 4000 years before Christ, especially in the working of the very refractory granites, basalts, and porphyries, which no unaided metal tools could possibly have cut. That jewels *fixed* in the rim of the metal tube were used, and not merely loose corundum or emery-powder, is shown by the fact that the scratch from a single projecting jewel can often be traced continuously round the spiral markings on the insides of the drill-holes.

It is not, however, only the mere technical details of the workmanship of this Tirynthian palace that bear strong witness to its early date, but also the methods of construction—the walls of sun-baked bricks set on a footing of stuccoed rubble, the use of wood instead of stone for the columns, and the magnificence of the walls lined with plates of bronze, *repoussé* and gilt.

Finally, nothing can be clearer than the evidence supplied by the semi-Oriental style of the wall-paintings, and the distinctly archaic character of the delicately sculptured alabaster frieze, studded with gem-like pieces of blue *κύανος*—exactly as was once the case with the central row of spirals in the well-known architrave from the doorway of the "Treasury of Atreus" in the British Museum, the remote antiquity of which is disputed by no one. In fact the methods of execution, the system of its construction, and the style of its decoration all combine to show that we owe to Dr. Schliemann and Dr. Dörpfeld the discovery of an almost new phase of prehistoric Greek art.

J. H. M.

ON VARIATIONS OF THE CLIMATE IN THE COURSE OF TIME[1]

If we examine the meteorological charts of Norway we observe at once what a great influence the sea and the mountains exercise over the climate in various parts. Nearly all the climatological lines run more or less with the shape of the coast, so that we encounter far greater variation when proceeding from the centre coastwards

[1] The following is a short abstract from various papers, viz.: "Essay on the Immigration of the Norwegian Flora during Alternating Rainy and Dry Periods" (Christiania, 1876). "Die Theorie der wechselnden kontinentalen und insularen Klimate," in Engler's *Botanische Jahrbücher*, ii. (Leipzig, 1881). "Ueber Wechsellagerung und deren mutmassliche Bedeutung für die Zeitrechnung der Geologie und für die Lehre von der Veränderung der Arten," in *Biologisches Centralblatt*, iii. (Erlangen, 1883). "Ueber die wahrscheinliche Ursache der periodischen Veränderungen in der Stärke der Meeresströmungen" *l.c.* iv. (Erlangen, 1884).

than from south to north. In keeping with the same are the variations of the flora.

The plants of Norway may be divided into certain groups of species, the species belonging to the same group having a somewhat similar extension, whilst each of these groups of species is confined to special climatological conditions, and is only found in those parts where such prevail. The Norwegian flora is in the main monotonous. On the mountains large areas are covered with only a few lichens, mosses, and heather, or copses of dwarf birch, juniper, and willows; lower down the forests are formed of birch, fir, and spruce, and have a monotonous flora, viz., heather and lichen in the fir forests, "blue" berries and a few kinds of moss in the spruce forests, whilst the west coast is covered with heather, and the numerous marshes with a vegetation, poor in species, of a few mosses and Carices.

But in spite of this general monotony of the flora of the mountain wastes, with their grayish-yellow lichens, grayish-green and green copses of willows or dwarf birch, there are certain places, particularly on slaty ground, where a rich vegetation may be found. It consists of small perennial plants some inches in height, and which are particularly distinguished by their copiousness of flowers, which are very large in proportion to the size of the plant, and have very pure and lovely colours. Outside Norway we also encounter these plants in Arctic regions, and the Alpine flora of these slaty tracts is therefore of Arctic character. But not all slate mountains have such a varying flora. The coast climate is, in consequence of the mild winters, when the temperature frequently changes, destructive to these plants, which shoot at a very low degree of heat. It is for this reason that, when we mark those places on the map which have a rich Alpine flora, they lie scattered as oases over the land with great spaces between them, but always sheltered from the sea-winds, *i.e.* on the east or north-east side of the highest mountains and greatest glaciers, which act as barriers against the mild climate of the coast. In these places the botanist may fancy himself transferred to Spitzbergen or North Greenland; he finds the principal plants encountered there, and if we follow the Arctic flora to Spitzbergen we find that here also it shuns the sea, and is most copious in the bottom of the fjords.

In the lower districts, sheltered from the open sea, we find in favourable spots another group of plants which also shun the coast, and which thrive on loose slates and warm limestone cliffs, or in screes of different kinds of rock, under precipitous mountains, facing the sun. These screes are generally full of bare boulders at the bottom, but in the finer debris higher up grows a wreath of green underwood, formed of tender deciduous trees and shrubs, hazel, elm, lime, maple, dog-roses, *Sorbus Aria*, *Prunus avium*, wild apple, &c., as well as a number of highly-scented Labiatæ, several Papilionaceæ, grasses, and a great number of other plants, together forming that part of the Norwegian lowland flora which shuns the open sea-coast, and prefers the fjords and the sunny valleys. But even this flora has a scattered extension. It is richest in the tracts around Christiania, and becomes poorer westwards along the coast, disappearing almost entirely on the coasts of the province of Bergen; but at the bottom of the Sogne and Hardanger, and along the Throndhjem fjords we find the same flora, and that in spite of these parts being entirely separated by enormous mountains.

Near the open sea the flora becomes poorer in species, most of those characteristic of the interior disappearing, whilst their number is not by far made up by those belonging to the coast. Here we shall only name a few of the coast plants, such as the holly, the ivy, and the foxglove, whilst in place of the *Primula veris* of East Norway we have the *Primula acaulis* of the west coast. In the woodless tracts of the coast the heather predominates, and besides the ordinary common one we find two other species. This group of plants belongs exclusively to the south and west coasts, and is hardly found north of the Throndhjem fjord. Most of its species are not found near Christiania, but they reappear in the south of Sweden. Some, however, are in Scandinavia only found on the west coast of Norway, and we must travel to the Faroe Islands, Scotland, England, and Belgium to re-encounter them.

We have thus seen that the Norwegian flora consists of groups of species which make different demands as to climate. If we were to colour a map according to the places where certain groups are most copious, we should at once discover that they had a scattered distribution. We should find the same colour here and there, in smaller or larger patches, but those of the same colour would be separated by great spaces of a different tint.

At one time botanists were satisfied with explaining the distribution of species through soil and climate, but as the study of their appearance proceeded it was discovered that there were great gaps in the extension of many. And these gaps were often so great that scientific men were obliged to resort to explaining the same by maintaining that such species were created in places far apart. But since the doctrine of the origin of species by descent has been accepted, such an explanation must be rejected. There remains, therefore, only two ways in which to explain these things. Either wind, animals, or sea-currents are capable of carrying the seed of plants at once across such large areas that the gaps in the extension can be explained by the means of transport at work at present, and there are even those who still believe that this is the case. In certain instances this explanation is indeed the only one possible, when, for instance, it concerns the flora and fauna of the oceanic islands which have never been connected with the great continents, and still have species more or less related to those of the mainland. But such a sudden migration is very improbable, and may even be dispensed with altogether, as we shall presently show, when it is necessary to explain such gaps in the extension of whole groups of species as those we have pointed out above in the flora of Norway.

We have, besides, another explanation of this problem, first advanced by Mr. Edward Forbes, who maintained, in common with most modern botanists, *that the climatic variations of the past are reflected in the fauna and flora of the present.* He was, we believe, the first *savant* who demonstrated that the Glacial Age has left its distinct mark on the flora of the present day. Arctic species are found on mountains in temperate climates. During the Glacial Age these species grew in the plains at lower latitudes, but as the climate became milder they receded gradually to the far north and the high mountains. In the warm plains they had to give way to the new immigrants, and this is the reason of our discovering hyperborean plants on the mountains of Europe.

If now we were to apply this explanation to the scattered extension of the species in Norway, we must bear in mind that the distances here are smaller, although at times there are several degrees of latitude between the places where the same appear. We must, therefore, see if an acceptable explanation of the extension of the Norwegian flora can be made by means of geology, and if the same be supported by other circumstances.

It is not long since, geologically speaking, that the Scandinavian peninsula was covered with an inland ice, stretching right out to sea, above which only solitary mountain-tops rose, like the "nunataks" in Greenland. It is evident that the majority of the present flora could not then exist in Norway; but the present flora is older than the Glacial Age, which is conclusively proved by specimens from the same being found in coal strata older than that period. Thus yew, fir, and spruce, hazel, willow, &c., have been found in old peat-bogs of England and Switzerland, for instance, which are covered by the bottom moraine of the inland ice. The present Norwegian flora, there-

fore, must have lived in other countries which were free from ice during the Glacial Age, and immigrated to Norway as the climate became milder and the ice receded. This is the reason of Scandinavia having no peculiarly characteristic species, *because the flora has immigrated from outside countries, and the time is so short since it settled in the country that it has not yet had time to produce new species.*

If we may now apply the geological theory of explanation to the flora, we come to the conclusion that the immigration took place during repeated changes in the climate. After several thousands of years with a severer climate which favoured the immigration and extension of northern and eastern species, other thousands of years followed with a milder climate. During this period fresh immigrants came from the south and south-west, compelling the older flora to retreat. In this manner the climate must have changed several times since the Glacial Age, and the distribution of the plants must have changed in accordance therewith. The periods of variation are reflected in the present flora, and it is the former which have led to the great gaps in the extension of coast as well as inland plants. The sunny screes, the slate districts, and the moist coast tracts are asylums where the different floras have found refuge. In the intermediary parts they have been dislodged by the newcomers. But certain species, being indifferent to the variations, extended constantly, at the expense of others, *and this is the reason of the Norwegian flora being so monotonous.*

In order to test the accuracy of this assertion we shall first turn to the peat-bogs and examine their structure. We shall, for comparison's sake, also examine the Danish ones, which are well known from the researches of Prof. Steenstrup.

In the forest and mountain districts of Norway there are innumerable marshes. In the forest districts most of them are now comparatively dry, the heather and wood covering parts of the bog, and on the surface of the latter tiny mossy knolls are often found, in the middle of which stands the old stump of a tree. An examination of the structure of the peat layers—which is easily made with a bore—shows that previous to the present time, when the surface is generally more or less dry, there was a period when the bog was much more watery. Under the present conditions the growth of the peat is arrested, at all events in dry places. But just below the lichen and heather-covered surface we find on boring a pure, unmixed white moss (Sphagnum). It is this moss in particular which has formed the peat in the Norwegian bogs; and in the upper layers—only one or two feet from the surface—flint implements from the Stone Age are often found. At the period this upper layer of Sphagnum was formed the bogs were woodless because they were too watery. We see, therefore, that the peat in these bogs has not grown very much within historical times, and that the layer of stumps of trees, which are found on the surface in the knolls, indicates an arrest of the growth of the peat, the duration of which may probably be measured by many hundreds, perhaps by thousands, of years. It might be argued that the present drier state of the bogs was simply due to the circumstance that the peat had grown so high that the moisture had run off. But this is not an acceptable explanation, because if we bore deeper in the peat we find that the oldest bogs are built of four layers of peat, *and between these stand three layers of stumps, so that these bogs are for the fourth time covered with trees since they began to form.* And as most of the bogs, if not all, are at present drier than they were before, the theory of merely local variations of the moisture is also insufficient to explain the phenomena. It remains, therefore, only to assume *that periods of dry and wet have alternated during ages.* The peat layers generally belong to the latter, and the stump layers speak of drier periods, when the bog was covered with trees.

Of these four layers of peat, which in some places measure upwards of twenty-six feet in thickness, only the two youngest inclose, as far as the researches in Norway go to show, remains of foliferous trees sensitive to cold. And this justifies the assumption that they correspond to the four layers which Steenstrup has shown in the bogs of Denmark, and which appear like geological strata with distinct fossils, viz., the aspen, the fir, the oak, and the black alder. This comparison of the peat layers of Norway and Denmark is further supported by the circumstance that layers of stumps are also found in the Danish bogs, and here, too, they stand between the peat layers of the various periods. They indicate long periods, during which also the Danish bogs were dry and partly covered with forests when the peat ceased to grow. But during these dry times the flora was changed through the immigration of new species, and when a wet time again set in, it was other trees which grew around the bogs, and which spread their boughs, leaves, and fruits over the watery bog, and the remains of which were buried by the growing layers of peat.

In this manner the structure of the peat confirms the conclusion to which the distribution of the flora pointed, and if we take the fossil plants and marine shells to our aid we may explain the gaps in the extension of the species without assuming long transports of seed.

In the freshwater clay of Scania and Seeland, Prof. Nathorst has discovered numerous remnants of Arctic plants. This clay lies *below* the peat. When it was deposited in the cavities of the old bottom moraines of the inland ice, not only the dwarf birch, but even hyperborean plants, such as the Arctic *Salix polaris* and others, flourished in the southernmost parts of Scandinavia: *therefore the Arctic flora was the first which immigrated into Scandinavia.* It entered whilst the climate was very severe; but the climate became milder and more moist: the peat began to form; then the aspen and birch entered, and, later on, under varying conditions of moisture, the fir and the spruce, with the flora of the mountains and forest glens, a series of species which have not yet been mentioned, viz. Mulgedium and Aconitum, many great ferns and grasses, wood-geraniums, and lychnis, &c. But the climate became warmer and warmer; and finally the foliferous trees, more sensitive to cold, entered, viz. the hazel, the lime, the ash, the oak, the maple, and a number of others from warmer regions. In the province of Bohus quantities of stones of sweet cherries are found in many places, in peat, where this tree is now extinct; and in the Norwegian peat-bogs hazel-nuts are very frequent in a certain layer, not only in the interior of the great coniferous forests, where not a single hazel-tree is found, but even in the heathery, woodless coast-lands. It will, therefore, be seen that the hazel and the sweet cherry were then very plentiful, and from this we may justly conclude that the trees, and shrubs, and herbs which thrive in their company were also once far more plentiful than at present. *It is this flora which has found an asylum in the above-mentioned screes.*

Following the period when Southern Norway was covered with foliferous forests to a far greater extent than now came a warm and moist one, in which the peat again began to grow. At that time the coast oak (*Quercus sessiliflora*) was far more frequent than at present, judging by the evidence of the peat-bogs, and at that time, the shell deposits inform us (as shown by Prof. M. Sars), the present marine animals of the west coast were found in the Christiania fjord. *And there is every reason to assume that the present flora of the west coast immigrated thither at that period from the south of Sweden along the Christiania fjord to the west coast.*

New changes again set in, with new immigrants, and finally came the present age with its comparatively dry climate. But all these events are prehistoric, as is shown by the stone implements lying in the uppermost peat layer, close under the surface.

Thus, the remains of plants and animals in clay, peat, and shell deposits inform us *that the gaps in the extension of the species in Norway may be explained by the varying events of times long gone by.*

Since the Glacial Age the relation between sea and land in Norway has changed. Formerly the sea was in some places upwards of 600 feet higher than at present.[1]

The clay at that time deposited on the sea-bottom, and the shell deposits formed near the shore, contain, as Profs. M. Sars and Kjerulf have taught us, remains of Arctic animals even in the southernmost parts of the country. There is a difference of opinion between *savants* whether this alteration of the shore-line is due to a rising of the land or the sinking of the sea, or to both. There is further some dispute about the manner in which the level became altered, some maintaining that it took place suddenly at intervals, whilst others believe that it is the result of a gradual and continuous process. The marks left by the sea seem at first glance to corroborate the first of these theories. Thus, in the lower parts of our valleys we find along the river-courses terraces of sand, pebbles, and clay, one behind and above the other right up to the highest old shore-line. The terraces, of which Kjerulf, pre-eminently amongst others, has given us particulars, have an even surface and a steep declivity outwards against the mouth of the valley. They contain sometimes remains of sea animals. Under a higher level of the sea the river carried down sand and gravel to its mouth, just as in the present day banks and bars are formed at the estuary of our rivers. And the terraces seem to indicate that the changes in the level were broken by periods of rest. During the latter the river had time to form a bank, which rose comparatively rapidly; the next period of rest gave occasion to the formation of another terrace, and so on. But this theory has to combat many obstacles, because the terraces lie often, as Prof. Sexe has shown, even in valleys situated near each other, *at different elevations*. The professor is of opinion that step-like terraces may be formed even under a gradual and steady rising, if the carrying-power of the river is subjected to changes. Our theory may therefore probably also be applicable for explaining the terraces, because, if long periods with milder climate have alternated with others whose climate was more severe, it is evident that the volume of water, and thus the carrying-power of the current, may have altered. Perhaps the rivers have at certain times carried down floating ice, at others not, and the thaw in the spring must have increased the carrying-power. We can thus understand why the corresponding terraces in valleys near each other do not always lie at the same elevation. Their rivers differ in size, and when the carrying-power diminishes a big river will retain the strength to form a terrace longer than a small one.

Besides these terraces, which are particularly conspicuous in the short steep valleys on the west coast of Norway, and on account of their regularity must excite the admiration of every one who sees them, there are other equally striking marks of the old sea-levels, viz. the so-called "Strandlinjer"—shore-lines—which are known chiefly through the researches of Prof. Mohn and Dr. Karl Pettersen.

When travelling through the fjords and sounds, particularly in Northern Norway, one sees here and there horizontal lines drawn along the mountain-sides, sometimes several hundred feet above the sea. They are not always equally marked, but appear often remarkably clear; sometimes they look like roads or railway-lines. They are always horizontal, or nearly so, and must, therefore, be remains of an old sea-shore. Often two parallel lines are seen running one above the other in the same place; and on closer inspection it will be discovered that they are hollowed out of the rock itself. They have a surface sometimes many feet broad, and are bounded behind by a more or less steep mountain-wall, forming thus horizontal incisions in the same. The shore-lines have also been brought to prove that the rising was broken by periods of rest, during which the sea had time to hollow out the rock; but I am of opinion *that they could be formed, too, under a gradual rising, if the climate be subjected to periodical changes.* The shore lines belong to the northern parts of the country and the deep fjords, where the winter cold is more severe, and they are only found in districts where there is a tide. They seem to have been blasted out by the influence of the cold. At high tide the sea-water fills the holes and fissures in the rock, and when the tide recedes it is left in the same. In severe winters the water will freeze, and thus burst the rock. During the rising of the land, shore-lines will be broken out in this manner, as long as the erosion is able to keep pace with the rising. When the climate becomes milder, a time will come when the erosion is unable to continue. Then the shore-lines will be lifted up above the level of the sea, and out of the reach of the blasting influence of the water. If next, after thousands of years, when the land has perhaps risen fifty or a hundred feet, a period follows with a severer climate, a new shore-line is formed below the former.

The shell-banks, too (*i.e.* deposits of shells of marine animals living in shallow water near the shore) lie, as Kjerulf has shown, in the Christiania fjord at different levels, the oldest at heights of from 540 to 350 feet, and the youngest between 200 and 50 feet above the present level of the sea. But between 350 and 200 feet none has been found. In the neighbouring Swedish province of Bohus they are found at all elevations, even between 350 and 200 feet, and it must therefore be assumed that local causes, as, for instance, the ice formation in the more closed Christiania fjord, destroyed the shell-banks when they reached the shore-line, at a period when the land lay 350 to 200 feet lower in relation to the sea than at present. According to the evidence of the peat-bogs, there is reason to believe that this part of the rising occurred under a more severe climate.

It is therefore seen that all the facts which have been advanced in order to prove that the rising was broken by periods of rest may be easily explained, *if we assume that the land rose gradually and steadily under periods alternating with milder and severer climates.*

The University, Christiania A. BLYTT

(*To be continued.*)

[1] The depth of the peat in the parts which were formerly below the sea increases with the height above its surface, because the formation of the peat commenced long before the lowest-lying parts had risen above the surface. From the remains of plants found in the various peat layers we may therefore learn how the Norwegian flora was composed during the various phases of the rising of the land.

HYPERTRICHOSIS

I THINK all naturalists, and anthropologists in particular, will be interested in the cases of human hypertrichosis now on view at the Egyptian Hall, Piccadilly. I myself spent two hours with them on Saturday last.

This family of hairy people have been at the Court of Burmah for four generations. Crawfurd saw Mahphoon, the old woman now exhibited, an infant in 1827; the family was described by Col. Yule in his narrative of a Mission to the Court of Ava in 1855.

It is singular that the hypertrichosis of Mahphoon's grandparent should be continued not only to herself but to her son, Moung Phoset, also exhibited, inasmuch as one of the parents has always been an ordinary comparatively hairless Burman, so far as the face and body are concerned.

Mahphoon is now an old blind woman, but very lively, full of fun, and an inveterate chewer of betel; her face

and ears are entirely covered with hair, particularly thick on the nose. Her son, Moung Phoset, is more hairy on the face and ears than his mother—probably her locks are somewhat thinned by age—his forehead is densely clothed with hair, which, when combed over his face, entirely hides his features, the hair being 12½ inches in length; he parts it over the eyebrows and passes it behind his ears; it is also very long on the nose, and being parted in the middle and falling over the cheeks gives his face a most remarkable resemblance to that of a Skye terrier. The suggestion was so strong on my mind that I could scarcely divest myself of the canine idea.

The whole of his body is clothed with soft hair some inches in length, but I am informed that he has usually had this cut from time to time, so that its natural length is not apparent. The hair of Moung Phoset and of his mother Mahphoon is very soft and wavy, of a brown colour, and utterly unlike the coarse black hair of the ordinary Burman.

Capt. Paperno, who obtained them, and has been fifteen years in Burmah, informs me that the dentition of all these hairy people has been imperfect, whilst their less hairy brethren and sisters have had perfect teeth.

I have examined a cast of Moung Phoset's mouth. In the upper jaw he has but two canines and two large incisors, in the lower jaw two canines and four small incisors; the premolar and molar teeth are quite absent.

A nephew of Mahphoon, who is exhibited with them, has the appearance of an ordinary Burman only.

I believe that it is owing to the enterprise of Mr. Farini that we are enabled to see this singular family in London.

They are both far more hairy than Krao, who was exhibited in London some time since, and is now at Paris in good health; she was obtained from a district east of Burmah, and north of Siam; the features of the Burman family are so obscured by hair that I could not ascertain whether there was any resemblance to those of Krao, nor even whether they were Mongoloid.

Moung Phoset has been well educated, writes fluently in the Burman character and language, and possesses considerable power in the delineation of objects; like many Burmans he is tattooed from below the waist to above the knees

I have seen a photograph of a brother of Mahphoon now dead; he was quite as hairy as his sister, but the peculiarity did not, I understand, extend to the whole of the family.

Chirbury, Beckenham, Kent

NOTES

PREPARATIONS are being made by Parisian men of science for the celebration of the 100th anniversary of the birth of M. Chevreul, on August 31 next.

A REGULATION as old as the French Academy of Sciences has just been broken through in Paris. Women have hitherto been excluded from the sittings of the Academy, but at the meeting of the 28th ult. the interdiction was raised in favour of Mdlle. Sophie Kowlewska, Professor of Mathematics at the University of Stockholm, and daughter of the eminent palæontologist. Admiral Jurien de la Gravière, who presided, welcomed her in graceful terms, and said that her presence should be a cause of pride and pleasure, not only to the mathematicians present, but to the whole Academy. As she entered, the whole of the members rose to salute her. She took her place between Gen. Faye and M. Chevreul.

ACCORDING to official decree, the Tokio University and the Imperial College of Engineering having been amalgamated into the Imperial University of Japan, they now cease to exist. The new University comprises five colleges or sections: (1) Law; (2) Medicine; (3) Engineering; (4) Literature; (5) Science. Each of these, as well as the whole institution, is placed under a Japanese director. The director of the Science College is Prof. Dairoku Kikuchi, a Cambridge Wrangler, and the same gentleman is acting for the present as head of the Engineering College also. The large and splendid buildings erected for the Engineering College—the finest pile of European edifices in Japan—will, it is said, be used in future as a school for the children of nobles.

HERR FENNEMA, a mining engineer at Buitenzorg, in Java, has made some observations on the recent volcanic eruptions in that island which are of interest as setting at rest a matter on which some doubt has existed. On the authority of Junghuhn, the general belief has been that in historic times all the volcanoes of Java (and of Sumatra it may be added) had thrown out solid matter only, and never those streams of lava which are so characteristic of most eruptions. But a careful examination of Smeru and Lemongau during the catastrophe of April last year shows that this notion must be abandoned as incorrect. The former is not only the highest but also the steepest in Java. From 700 to 1400 metres the slope is about 6°, up to 2100 it is 20°, and from 2100 to 3671 metres it is more than 30°. For a considerable way from the summit the striking cone consists wholly of the detritus thrown out regularly by the almost uninterrupted activity of the crater. Up to April 1885 the existence of torrents of lava was unknown. On the 12th-13th of that month a stream appeared on the south-eastern side, and forced the residents on the plantations lower down to fly. The stream increased for several days, until it reached a height on the mountain-side of about 2100 metres from the level of the sea. The loss of life was due to the avalanche of stones sent down the steep sides of the mountain by the stream. Similarly, at the same time, Lemongau threw out a lava stream, but there was a curious difference between this and the one issuing from Smeru—the latter was andesitic in its character, while the former was basaltic.

WE have received from Mr. Henry Farrar, 6, Hanway Street, W., photographs, seven in number, selected from a very extensive collection taken by a native of India, Lala Deen Diyal. One consists of the whole view of the rapids of Chichai waterfall, near Reira, which are 400 feet deep; another, a river view at Indore. The photographs themselves are exquisite; in looking at some of them one might imagine one's self in the tropics surrounded by the wonderful vegetation of that region. The tone of them is very fine, especially in the one "Channel below the Keuli waterfall, near Reira," the velvety appearance of the vegetation on the hillsides is in strong contrast with the sharp and clear detail of the white and waterworn stones in the river bed. To the various lovers of nature as well as students of art and archæology a possibility of getting quite perfect photographs of the natural and artistic wealth of India at a low price should be very welcome.

IT is stated that the explorations for coal conducted by Dr. Warth in the Salt Range in the Punjab have proved so satisfactory that the Government is now arranging for the practical working of the seams. Dr. Warth estimates that over one million tons are underlying the plateau at Dundote. The coal is not of the first quality. It contains iron pyrites and is very friable, but it is believed that it will be very useful for the North-Western railways.

WE have received several communications relating to the letter signed "P." in NATURE for May 27, p. 76, on "Male Animals and their Progeny." Mr. Arthur Nicols has noticed several times a common cock marshalling a brood of chicks,

picking up food for them, calling them together on the approach of danger, and even "brooding" them at night. A case was communicated to him a few years since by Dr. James Gale, in which a turkey cock incubated six fowl's eggs during the whole period, successfully producing three chickens, and continuing to treat them with all the care of a hen. The hen turkey with which he had been mated was unfortunate in her brood, and this circumstance appears to have impelled him to take possession of the fowl's eggs. Besides the fact that in a considerable number of species the male not only takes his turn at incubation, but continues, equally with the female, to feed the young after they have left the nest, we have the case of the male emu, who performs the task of incubation alone. The male ostrich, too, as observed in a semi-domestic state, undertakes a large, and sometimes it would seem the entire, share of nidification. When the pair of Apterix in the Zoological Gardens nested, the male alone sat assiduously during fifteen weeks on the two eggs, which, however, proved infertile. A correspondent from Melksham also records a case in which a bantam cock brought up a brood of chickens, the mother having died when they were two days old. Mr. Hyde Clarke quotes instances of similar care bestowed by male dogs and cats in Turkey on the young.

The curious case of the emu is described in a letter from Mr. Alfred Bennett, who had an opportunity of watching the habits of this bird, which was, during several seasons, successfully bred by his father in Surrey. The hen bird, says Mr. Bennett, begins to lay about the end of October or beginning of November, and as each brood consists of twenty eggs or more, laid at intervals of two days, the process takes about six weeks. Before it is completed, the cock bird begins to sit. The eggs laid subsequently are deposited by the hen by the side of her mate, who puts out his foot and draws them under him. As soon as the eggs begin to hatch it is necessary to isolate the hen, as she fights furiously with her mate, and would to all appearance kill the chicks if she were allowed to get at them. The whole of the tending of the young is performed by the male bird.

An opah, or king-fish (*Zeus luna*), which is an exceedingly rare fish, was recently captured off the Shetland Islands and brought to the Colonial and Indian Exhibition for inspection. The specimen, which is in perfect condition, measures about 5 feet in length, and weighs 160 pounds. The colours of the sides and back are dark green intermingled with gold and purple, while the irides are red. The opah seems to possess peculiar migratory propensities, being found at various parts, even in Eastern seas. The habits of this fish seem to be little known, but Mr. W. August Carter, of the Colonial and Indian Exhibition, states that, according to inquiries and investigations he has made, the opah varies its diet according to the locality it inhabits, and that when visiting the British Islands it feeds chiefly upon herrings and cuttlefish.

In one of the Courts of the Colonial and Indian Exhibition is a very fine raven, presented by the Maclaine of Lochbuie. This bird, on account of its sagacity, creates much amusement and interest amongst visitors. On being fed it partakes of so much of the food as it requires, then hides the remainder in certain parts of its habitat beneath pieces of paper and other articles that happen to be about. As many as four hiding-places are made use of by the raven for storing its food, which it exhumes when desirous of feeding. It is a curious fact that the raven only resorts to such stratagems when being watched by the public, at other times this sagacious bird consumes its meals in their entirety at one time.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. Albert Thorne; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. S. R. Hicks; a Prairie Wolf (*Canis latrans* ♀) from Winnipeg, presented by Mr. Gerald F. Talbot; a Common Fox (*Canis vulpes*), British, presented by Mr. A. Browning Priestley; a Brown Bear (*Ursus arctos*) from Asia, presented by Capt. Asher Smith; a Stein-bok Antelope (*Neotragus tragulus*) from South Africa, presented by Mr. W. J. Robertson; two Violaceous Night Herons (*Nycticorax violaceus*) from South America, presented by Dr. A. Boon, F.R.C.S.; a Mona Monkey (*Cercopithecus mona*) from West Africa, a Grey Squirrel (*Sciurus cinereus*) from North America, a Greater White-crested Cockatoo (*Cacatua cristata*) from Moluccas, deposited; six —— Sousliks (*Spermophilus* ——), five American Flying Squirrels (*Sciuropterus volucella*) from North America, two Glass Snakes (*Pseudopus pallasi*) from Dalmatia, purchased; two Mule Deer (*Cariacus macrotis* ♀ ♀), a Yak (*Poephagus grunniens* ♀), four Long-fronted Gerbilles (*Gerbillus longifrons*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

Method of Correcting for Differential Refraction in Declination.—Mr. McNeill, of the College of New Jersey, Princeton, has published in the *Astronomische Nachrichten*, No. 2735, a method of correcting micrometer observations for refraction which was devised originally for the diagonal-square micrometer, but is applicable also to the ring micrometer and others of the same class. In this method the correction to the difference of declination is not determined separately, but the true difference is directly determined, the corrections being applied to the logarithms in the course of the computation. Mr. McNeill shows that if we apply the number given by

$$M\kappa(\tan^2\zeta\sin^2 q + 1)$$

to the logarithm of the half chord traversed by the star, and the corresponding number deduced from

$$M\kappa(\tan^2\zeta\cos^2 q + 1)$$

to the logarithm of the apparent distance, measured on a circle of declination, from the point of reference in the micrometer, the result obtained will be the true distance corrected for refraction. In the above expressions M is the modulus of the common system of logarithms, κ the constant of differential refraction, ζ the true zenith distance, and q the parallactic angle. It is then only necessary to tabulate the expression

$$M\kappa\{\tan^2\zeta\cos^2(p - q) + 1\}$$

with arguments $p - q$ and ζ, adding subsidiary tables giving barometer and thermometer factors, in order to obtain the quantities required (by making p alternately $= 90°$ and $= 0°$) to correct the micrometer observations for differential refraction in declination. This Mr. McNeill has done, and his tables will doubtless be of much use to observers using the class of micrometer to which the method is applicable.

New Minor Planet.—A new minor planet, No. 259, was discovered by Prof. C. H. F. Peters, Clinton, New York, on June 28. Minor planet No. 253 has been named Mathilde.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 JULY 11–17

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 11

Sun rises, 3h. 58m.; souths, 12h. 5m. 12·6s.; sets, 20h. 12m.; decl. on meridian, 22° 6′ N.: Sidereal Time at Sunset, 15h. 30m.

Moon (three days after First Quarter) rises, 15h. 49m.; souths, 20h. 38m.; sets, 1h. 22m.*; decl. on meridian, 15° 14′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 17	13 51	21 25	17 0 N.
Venus	1 32	9 30	17 28	20 42 N.
Mars	11 8	17 2	22 56	1 59 S.
Jupiter	10 31	16 42	22 53	1 22 N.
Saturn	3 30	11 39	19 48	22 25 N.

* Indicates that the setting is that of the following morning.

GEOGRAPHICAL NOTES

THE report published by Lieut. von Nimptsch, of the German army, gives some very interesting details of the journey he made with Herr Wolff, a traveller in the service of the Congo Free State, and which has resulted in the discovery of a river likely to be of material value to traders with the Congo. The Congo, in its course from the south-east, makes a very wide bend to the north, and then descends again to the Atlantic, a very large tract of country being embraced in this curve. Within this is the River Kassai, which Lieut. von Nimptsch regards as being "of even greater importance to commerce than the Congo itself." Describing their journey he says that, as far as Luebu, the Kassai flows through wide plains, well adapted for cultivation and pasturage, and forests of palms and gutta-percha trees. There are many villages on the banks, and the travellers met with great civility in all of them save one, the inhabitants of which fled at their approach. "One tribe," adds Lieut. von Nimptsch, "was remarkable for its joviality. The natives accompanied the steamer in their canoes, and when we could, organised dances and songs in our honour." There is a great deal of ivory all along the Kassai, and large pieces of the finest quality were readily given in exchange for empty boxes and tins. They discovered several affluents of the Kassai, and they calculated that they were navigable for a distance of 250 miles. "But the most important affluent," the report goes on to say, "is that which Herr Wolff explored in the steamer *Vorwarts* during the months of February and March. He ascended this stream to a distance of 430 leagues from its mouth, and one of its northern affluents brought him to within a week's march of Nyangwe. He might have gone still further had his steamer not met with an accident, for there are no cataracts in this river. All this network of navigable water, extending over more than 3000 miles, is most admirable, and in future it will be possible to travel eastward from the Atlantic, reaching Nyangwe and then Lake Tangyuteka by leaving the Congo at the mouth of the Kassai, without being obliged to ascend the whole of the former stream, thus avoiding the Stanley Falls."

A TELEGRAM from Zanzibar, of the 30th ult., states that Dr. Fischer had returned there. He has not succeeded in rescuing Herr Junker, the African traveller, who, when last heard of, was in the region north of Uganda.

A VERY interesting discussion which took place at the St. Petersburg Society of Naturalists after the reading of a paper by Prof. Beketoff on the South Russian steppes as compared with those of Hungary and Spain is now summed up in the *Memoirs* of the Society (vol. xxv. 2). The Russian steppes between the Pruth and Don, although belonging to the great "steppe region" of Grisebach, differ, however, from the remainder of the region inasmuch as they support agriculture without irrigation. They are akin, in this relation, to the Hungarian *puzhtas*. Being comparatively well watered, they belong more to Europe than to Asia, while those beyond the Don and the Volga bear a truly Asiatic character. As to the *disiertos* of Spain, they are more akin to the deserts of Africa than to the steppes of either Central Asia or Europe ; they have, however, some likeness to those of Transcaucasia. As to the causes of the want of forests in the Russian steppes, Prof. Beketoff explained it by the circumstance that, being covered with salt-clays, after the emergence from the sea, they were, first, inappropriate to the growth of forests. As the surface, however, lost by and by its salt and became covered with grasses, masses of ruminants were attracted into the region, and these ruminants prevented the appearance of trees, destroying them as soon as they appeared ; the climate being most unfavourable for the spreading of forests, the ruminants were also an important factor in the prevention of their appearance. The American buffaloes are an instance of the same influence. Dr. Woeikof fully confirmed the view taken by Prof. Beketoff, but pointed out that the burning of the steppes by man played also a most important part in the prevention of the appearance of forests. In America he was told of several instances where the trees began to grow as soon as the burning of prairies was stopped. Cattle are surely a great enemy of appearing forests. The very dry season of 1857 partly destroyed the cattle in Texas, and partly compelled to send it away to the mountains, and immediately the *Mesquita* began to spread in the prairies. It had time to take root before the cattle were brought back, and now it grows freely. The same has been seen on the *llanos* of Venezuela. The continuous wars and requisitions have led to a notable diminution of cattle, and now we do not find the boundless steppes of former times ; there are at least bosquets of trees. Mr. Jonas supposes that this change has even slightly modified the climate. Prof. Sovyetoff supported the same views, pointing out that cattle are an enemy not only of forests, but also of the grass covering of the steppes. He mentioned an instance of a large estate of 800,000 acres of virgin steppes in Taurida, where nearly half a million of sheep are grazing. The grass vegetation on these steppes has become strikingly poor, so that the cattle-owners calculate that for each sheep they must have 4·6 acres of grazing-land, 21·6 acres for each head of horned cattle, and 27 to 32 acres for each horse. The black-earth soil, when continually trampled on by the sheep, hardens as well as a clay soi would harden ; the soil is thus no more aërated, and becomes unable to support a rich grass vegetation.

THE *New York Times* announces that Lieut. Schwatka, the Arctic explorer, has accepted a commission from that paper to explore the southern coast of Alaska and to attempt an ascent of Mount St. Elias, the highest peak on the North American continent. Mr. William Libbey, Professor of Geography at Princeton College, has undertaken the charge of the scientific portion of the expedition, which left Port Townsend on the 14th inst.

THE three papers contained in the current number of the *Proceedings* of the Royal Geographical Society are of exceptional value and interest. Mr. James W. Wells describes the physical geography of Brazil in its broad features. He shows that the idea fostered by most maps that Brazil is a very mountainous country is wholly erroneous, and that it is mainly a vast plateau, excavated into numerous valleys by denudations, with relatively few purely mountain chains. As shown by the map accompanying the paper, the four main physical features of the country are (1) the vast, low-lying, flat plains of the Amazons, and the flat, grassy plains of the Paraguay ; (2) the elevated highlands that extend over the greater part of the empire ; (3) the higher lands constituting the watersheds of the principal rivers ; and (4) the groups of mountain ranges consisting of primitive rocks of purely upheaved strata. Mr. Wells then takes the three great hydrographic sections of Brazil, and treats of each in turn. Mr. Hosie describes one of the many journeys which he made through South-Western China while residing as agent at Chungking, the particular journey selected being one which carried him over new ground. A map which is appended shows the vast area covered by Mr. Hosie in his various journeys throughout Sze-chuan, Yunnan, and Kweichow provinces, and the very interesting observations on trade, present and prospective, in these regions show that his commercial duties have not been forgotten in the ardour of exploration. Mr. Bourne writes a paper on Diego Garcia, the principal of the Chagos Islands, which have recently received much attention on account of their position near the Red Sea route to Australia. The writer visited this remote spot to study the fauna and flora, and to make a collection of the corals of this part of the Indian Ocean.

THE SUN AND STARS[1]

VIII.

FOR the purpose of this lecture I have ventured to make a revision of the classification which has been suggested by Dr. Vogel. I should tell you, with reference to this question of classification, that Rutherford started it; then the German physicist, Prof. Zöllner, recommended a certain line of arrangement which practically had been adopted by Father Secchi. I afterwards saw grounds for saying that that line of arrangement, or sequence, was apparently a very just one, because it seemed, from some considerations I brought forward, that it really arranges the stars in the order in which the various phenomena would be produced in the atmosphere of any one of them; that is to say, that it was a true evolutionary line starting from the conditions of highest temperature. Others have followed in the same track since, including Dr. Vogel; but, so far as I can make out, any credit which is due to the existing arrangement is due to Father Secchi and to Prof. Zollner.

I will give you the arrangement, which I think will perhaps bring the facts in the most clear way before you.

We have, then, the first class of stars with broad absorption-lines and very few of them, and a remarkable absence of general absorption at the blue end of the spectrum. Next we have a second class, in which the lines are more numerous, and they are thinner. In this class come our sun, Arcturus, Aldebaran, and Capella.

Then we pass from absorption-lines altogether, and in the third class we have stars with flutings, of which the darkest part and sharpest edge of the fluting lie towards the violet part of the spectrum. Of these stars we have α Herculis and α Orionis as examples.

Then we have another set of fluted stars in which the opposite holds good. The darkest part and sharpest edge of the fluting are to the right, towards the red end of each fluting. And the stars of this class are faint.

In those four classes we nearly exhaust all those forty or fifty millions of stars in the heavens which shine, and which we can study by means of a telescope.

Afterwards we come to stars with bright lines, or the fifth class; and this we must divide into two—A and B.

In sub-class A the bright lines are always lines of hydrogen, such as we have in the chromosphere of the sun. Many of these stars, as we shall see by and by, which are characterised by such a spectrum as this are variable stars; not all.

In sub-class B the lines are not lines of hydrogen, and I may say that up to the present moment the origin of these lines is not known. There are, I think, at the present moment about half a dozen stars known with spectra of this character.

So much, then, for a general view. We have four classes of stars determined by absorption—two, line absorption; two, fluting absorption; first, broad lines; second, thin lines; first, flutings with the sharp dark edge to the left; then, flutings with the sharp dark edge to the right. Then in the last class we leave absorption-lines altogether and get to bright lines, and we get two sub-classes—those which obviously contain incandescent hydrogen, and those which as obviously contain something else.

Just a word or two on each of these two classes.

The stars with dark thick lines can be best shown by this diagram, which I owe to the kindness of Dr. Huggins. You

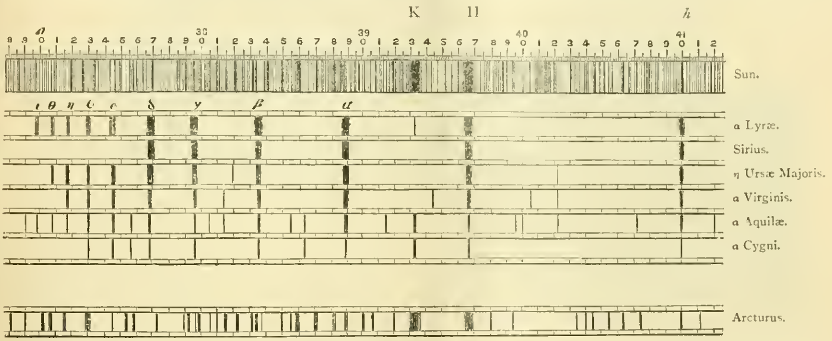

FIG. 22.—Stellar spectra (Huggins). In this diagram the spectrum of the sun is given at the top so that the spectra of the stars can be compared with it. The spectra of the stars are reduced from photographs, and the order of arrangement has been determined by the gradual thinning of the chief lines.

will see the difference between the thick absorption-lines and the thin ones, and you will remember that although stars may have the absorption-lines of identical wave-lengths, the thickness of these lines in the different stars may vary from one star to the other. Then we have the solar spectrum, the thickest lines of which are H and K, already referred to, in the ultra-violet portion.

The remarkable thing about the stars of the first class is that in some of them H is seen alone. In others H is seen with K thin, and in others H is seen with K almost as thick as itself. These lines are supposed to be due to the absorption of calcium. When calcium was studied in the laboratory a good many years ago, it was found that, at the temperature of the electric arc, the important brilliant line of calcium—the line which outshone all the others—was in the blue part of the sprectrum, and that the two lines which are most important, the two broadest lines, in the solar spectrum, are hardly seen at all in the spectrum unless the temperature of a very powerful induction coil be employed. Under these circumstances one may get the same relative importance given to the lines H and K in the violet which one gets with regard to the line in the blue as seen ordinarily, but only when the most tremendous means available to us are taken to secure what we consider to be the highest temperature.

On that ground it was prophesied that if the spectra of stars were ever photographed, probably some might be found hot enough to deal with those bright lines, H and K, in exactly the same way that the electric spark did; that is to say, that as in our laboratories we can get at a high temperature H and K obviously more brilliant than the blue line, whereas at low temperatures H and K are not seen at all, so we may anticipate similar results in the stars; if we can get stars very much hotter than any electric spark which we can obtain here, we might get H and K in different proportions, or each seen alone.

Now you see that prophecy has been fulfilled in this respect—that there are stars in which we get H alone without K, and we get different proportions of K added, as you can get different proportions of milk and sugar in a cup of tea.

Nor is that all. I am bound to tell you one other very curious fact. Since it was obvious when these stars were photographed that we were really photographing the result of an increased temperature; another prophecy was hazarded, and that was, that when, during an eclipse, the very brightest portion of the sun's atmosphere should be photographed in the ultra-violet and violet the spectrum would probably be very closely represented by the spectrum of these hottest stars. These photographs by

[1] A Course of Lectures to Working Men delivered by J. Norman Lockyer, F.R.S., at the Museum of Practical Geology. Revised from shorthand notes. Continued from p. 207.

Dr. Huggins of course only include the violet and the ultra-violet.

This is the place to tell you that in the eclipse of 1882 most of these lines which you see in the spectrum of Sirius and *α* Lyræ—lines which are entirely cloaked in the ordinary spectrum of the one, and in most of the other stars—was actually photographed in the hottest part of the sun's atmosphere during that eclipse; so that you see that there were two prophecies with regard to this set of lines, both of which were fulfilled.

Now, when in science a working hypothesis suggests a certain result under certain conditions—enables us to prophecy in fact, and the prophecy comes true (that is essential)—we have a right to believe that the hypothesis may be well founded.

Those, therefore, who hold that these differences are due to temperature, have considered their opinions to be considerably fortified by those two fulfilments of prophecy to which I have referred.

You see in the diagram that although in the upper spectra representing Sirius and *α* Lyræ the lines are very thick, as those particular lines thin out other lines come in; so that in passing down the diagram from the upper horizon to the lower one, we get two conditions of things—one which we leave when we get few lines thick, and another which we reach where we get a very considerable number of lines thin, as many people believe because these substances gradually, by reduction of temperature in the atmosphere of the star, have gone into combination with themselves or something else, and formed other more complex bodies, which give us of course new lines practically at the expense of the old ones. There then we get on that diagram representing a part of Dr. Huggins's magnificent work, the possible explanation of the passage from Class I. to Class II.

A reference to the two classes of absorption-spectra we owe chiefly to the work of Dunér and Vogel may very fitly follow these records of Dr. Huggins's work.

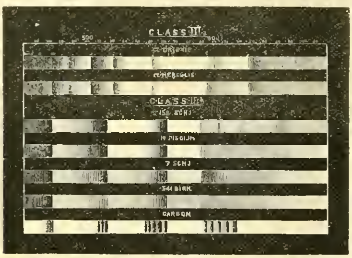

FIG 23.—Dunér's spectra of Class III. compared with carbon.

I did not tell you (there was no necessity for it at the time) that one of the rarest substances apparently in the atmosphere of the sun at the present time is carbon. There is a possible trace of carbon in the sun's atmosphere I think, but the assertion depends upon the existence of a single fluting, so far as observations go, in the ultra-violet part of the spectrum.

Now in these two classes of stars, Class III*a*. and Class III*b*. of Vogel, which I have called Class III. and Class IV. to make things easier, in the former we get a spectrum which at present has not been investigated; and we cannot say to what substances the absorptions in stars (there are hundreds of them mind you) which give you that spectrum is due.

But with regard to the stars of the latter class (and there are hundreds of them) they give us absorptions about which there is no question whatever. There the light of the star, instead of being absorbed by iron vapour, by hydrogen vapour, by calcium vapour, and by nickel, and by cobalt vapours and the like, as in the atmosphere of our sun, is absorbed by carbon vapour, and carbon vapour almost pure and simple, for when you have taken these big flutings out of the spectrum, there is little left—which means that when you get rid of the absorption of carbon in the atmosphere of those stars there is very little absorption left. I mean that the remaining spectrum is very simple.

I have already pointed out that it is fair to say that if our sun were hotter its absorption would more resemble the spectrum of its hottest portion, and there we have the spectra such as Dr. Huggins photographed for us in Class I. and Class II. I have just told you that there we really do get the same lines as in our sun during an eclipse, when we can best get at the spectrum of the hottest portion.

Are we to suppose then that if our sun was very much cooler than it is we should get the spectrum of carbon developed in this enormous way? That is a question which at present it is not possible to answer. It is quite probable, but then if that be so, you will see two things: first, that the carbon, *if it exists as such* in such enormous quantities in the sun at the present moment, must be so far outside the region of high temperature that it cannot absorb in that manner. The second point is that it cannot be that particular substance which gives us the continuous spectrum in the photosphere, because if it were we should be certain, I think, to get more indications of bright carbon vapour, both in the spectrum of sunspots and in the spectra of prominences than we do, so that although these stellar spectra may set us thinking about the sun, they are rather more important to us at the present moment for telling us what possibly is not rather than for what probably is.

With regard to the stars with bright lines, the only point that I need make about them now is that it is most important that every endeavour should be made to determine the origin of those bright lines which, as I have already pointed out to you, are not coincident with the lines of hydrogen. But I would rather say what I have to say on that subject in connection with the next part of the comparison which we are making.

In the spectra which have already been indicated to you nothing has been said about change of star-light except at long periods. It has been hinted that possibly a star which at one stage gives you a spectrum of very thick lines, may at other stages undergo changes which will make it a star of the second class, in which we have a greater number of thinner lines and so on.

Here the question of stellar evolution is suggested. On this subject I cannot enter, but a few general remarks may be made. We may say that we now know that comets are clouds of stones, and experiments, to which I will refer again later on, have been made which suggest that if nebulæ are of like nature the differences between cometary and nebular spectra may be explained by differences of temperature, that of the nebula being higher than that of the comet. Now comets ordinarily, *i.e.* when coolest, give us the spectrum of carbon, but when the temperature is increased, as it was in the case of the comet of 1882, sodium and iron are added. Imagine a comet with a nucleus the light of which is absorbed by ordinary cometary vapours, and we shall have the spectrum of a star of the fourth class.

On the nebular hypothesis, supposing, as seen above, that we started with ordinary cometary materials, then, on the beginning of a central condensation which in time is to become a star, as Kant and Laplace suggested, such central condensation should then give us a star of the fourth class. As the energy of condensation increased and the temperature got higher, the spectra would change through the third and second classes, till ultimately, when the temperature was highest, the first class spectrum would be reached. On the slackening down of the temperature of the now formed star, the spectra of the second, third, and fourth classes would then be reproduced, but, of course, now in the direct order.

Nothing so far has been said about changes which instead of taking millions and perhaps billions of years can be undergone in a few days, or weeks, or months.

Careful observations in the heavens have shown a great many years ago that a large number of stars are subject to a considerable change in their brilliancy. The most important work which has been recently done in what we may call the philosophy of variable stars we owe to the diligence of Prof. Pickering of Harvard Observatory in the United States. He has proposed a classification of variable stars, and for the purpose of this lecture I have just to make a slight alteration in his classification, as I did in the other one. First I will tell you broadly what the classification is, and then I will describe as briefly as may be some of the more important details which are of the greatest moment and interest. There is a whole mine of interest here which of course I cannot touch in the time at my disposal.

The first class of these variable stars then may fitly form what are called temporary or new stars—stars which as we have had evidence during the last few years—in 1866 and 1876, and at the end of last year, suddenly burst into visibility in the heavens as if they were new creations, last for a certain time,

and then die away. These stars have bright lines in their spectra.

The second class gives us those bodies which, although form do not appear and disappear with any suddenness comparable to that, yet indicate that there is something very extraordinary going on in them. They also belong to our fifth class of stellar spectra. They have bright lines as well as absorption-lines. These bright lines, however, only last for a short time; but bright lines there are.

Next we get stars not so interesting from the large point of view, in which we get considerable changes in their luminosity extending over very long periods, but their spectrum apparently does not change to any great extent. At least, no change of the spectra of these stars has yet been recorded.

After these, in Class IV. we get small irregular changes, and in fact, Dr. Gould—and there is no greater authority than he—says that every star in the heavens undergoes some slight change in its light at some time or other, but at all events those stars in Class IV. have undergone sufficient change to find themselves recorded among suspected variables, while the change actually has been so irregular that one has really practically not known to what class to assign them; and therefore they have a class of their own.

The next class of variables I will, on Dr. Pickering's authority, define as eclipsed stars: that is to say, in this class the change of light does not come from anything in the star itself, but from something that is happening outside it. What is happening you will see by and by.

Now with regard to our first class—the new stars. The accompanying diagram will give an idea of what has been recorded with regard to them. The information which the diagram affords will also give a pretty fair comparison between these variables and the other classes.

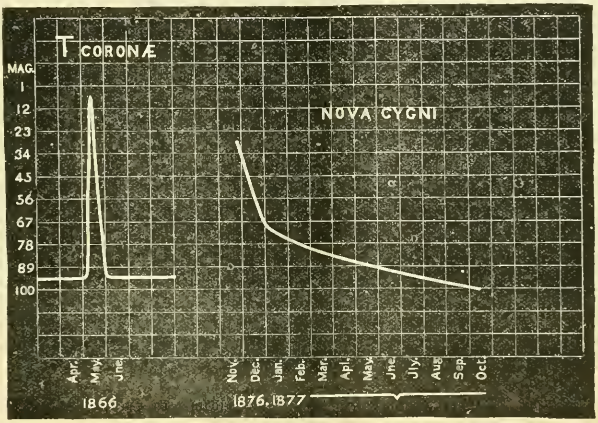

FIG. 24.—Light curves of T Coronæ and Nova Cygni.

In the year 1866 there was a star which had been chronicled for many years as a star between the ninth and tenth magnitudes; for this reason till 1866 its light curve is shown as a straight line. But suddenly, at the beginning of May 1866, this star suddenly burst up into a star of very nearly the first magnitude—between the first and the second. Many observations, as you may imagine, were made on it, and among them Dr. Huggins turned the spectroscope to it, and it was found that the difference between the star when it was between the first and second magnitude, and when it was between the ninth and tenth magnitude, was that in its spectrum when it was most brightly shining we got the spectrum of incandescent hydrogen. We had, in fact, the spectrum of the chromosphere of the sun. It was called "a world on fire." But you know that even the sun is not a world on fire. If it were, and if it were made of the best Welsh coal, we are told that it would last only a few thousand years. But at all events, whatever happened, there was an immense quantity of hydrogen suddenly rendered incandescent, which radiated its light to us.

Almost as suddenly this star went down again, and by the end of the month it had become a ninth or tenth magnitude star, and went about its ordinary business just as if the incident had never happened to it.

FIG. 25.—Cornu's spectrum of Nova Cygni.

Take the next star in 1876, ten years afterwards. It was called a new star—Nova in Cygnus. The point about this one is that it began suddenly as a star of between the third and the fourth magnitudes. It had had no former history. It had never been mapped. It did not visibly rise to the position of a third or fourth magnitude star from a lower level as the other one had done, but it burst out suddenly. Note the difference in its subsequent history. Its light curve, instead of going suddenly down as the one in Corona did in 1866, goes down gently, and takes nearly a year to get to the tenth magnitude. When it got to the tenth magnitude what happened to it? It gave the spectrum of a nebula. It had ceased to be a star. An interesting point is to inquire—unfortunately we shall never now know—whether or not that mass of matter did not exist as a nebula before 1876.

I have stated that, following close upon the publication of Dr. Vogel's paper on the new star, another paper announced the fact

that the new star had put on the appearance presented ordinarily by the so-called planetary nebulæ.

Of all the lines chronicled by Cornu and Vogel during its stellar stage, only one remained, that, namely, which the latter observer showed to be constantly increasing in brightness while all the rest were waning, and which, moreover, was coincident in position in the spectrum with that observed in the majority of the nebulæ.

The observations of such rare phenomena as the so-called new stars are of such vast importance, and will no doubt ultimately provide us with a clue to so many others of a different order, that we may well congratulate ourselves that this Nova was so well watched, and that there is such perfect completeness and unity in the chain of recorded facts.

It should have been perfectly clear to those who thought about such matters that the word star in such a case is a misnomer

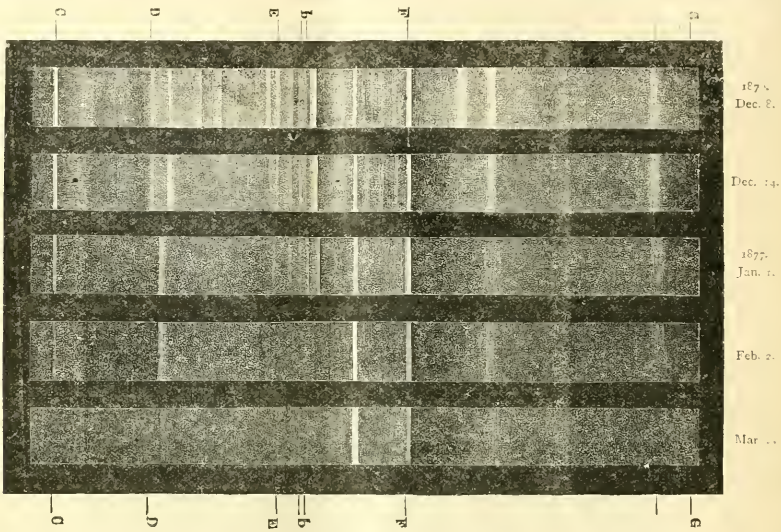

FIG. 26.—Vogel's spectrum of Nova Cygni.

from a scientific point of view, although no word would be better to describe it in its popular aspect. The word is a misnomer for this reason. If any star, properly so called, were to become "a world on fire," were to "burst into flames," or in less poetical language, were to be driven either into a condition of incandescence absolutely, or to have its incandescence increased, there can be little doubt that thousands or millions of years would be necessary for the reduction of its light to the original intensity.

Mr. Croll has shown that if the incandescence observed came for instance from the collision of two stars, each of them half the mass of the sun, moving directly towards each other with a velocity of 476 miles per second, light and heat would be produced which would cover the present rate of the sun's radiation for a period of 50,000,000 years.

A very different state of affairs this from that which must have taken place in any of the Novas from the time of Tycho to our own, and the more extreme the difference the less can we be having to deal with anything like a star properly so called.

The very rapid reduction of light in the case of the new star in Cygnus was so striking that I at once wrote to Mr. Hind to ask if any change of place was observable, because it seemed obvious that if the body which thus put on so suddenly the chromospheric spectrum were single, *it might only weigh a few tons or even hundredweights*, and being so small might be very near us. No motion, however, was perceptible, and Dr. Ball has since stated that he could detect no parallax.

We seem driven, then, from the idea that these phenomena are produced by the incandescence of large masses of matter, because if they were so produced, the running down of brilliancy would be exceedingly slow. J. NORMAN LOCKYER

(*To be continued.*)

FLAME CONTACT, A NEW DEPARTURE IN WATER HEATING[1]

IT is my intention to prove to you on theoretical grounds, and also by experimental demonstration, in such a manner as will admit of no possible doubt, that the present accepted system of water heating, by gaseous or other fuel, is a very imperfect means for an end, and is, both in theory and practice, essentially faulty. My statements may appear bold, but I come prepared to prove them in a manner which I think none of you will question, as the matter admits of the simplest demonstration. I will, in the first place, boil a specified quantity of water in a flat-bottomed vessel of copper; the time required to boil this you will be able to take for yourselves, as the result will be visible by the discharge of a strong jet of steam from the boiler. I will then take another copper boiler of the same form, but with only one-half the surface to give up its heat to the water, and will in this vessel boil the same quantity of water with the same burner in a little over one-half the time, thus about doubling the efficiency of the burner, and increasing the effective duty of the heating surface fourfold, by getting almost double the work from one-half the surface.

The subject is a comparatively new one, and my experiments are far from complete on all points, but they are sufficiently so to prove my case fully. As no doubt you are all aware, it is not possible to obtain flame contact with any cold, or comparatively cold, surface. This is readily proved by placing a vessel of water with a perfectly flat bottom over an atmospheric gas-burner: if the eye is placed on a level with the bottom of the vessel a clear space will be seen between it and the flame. I cannot show this space on a lecture-table to an audience, but I can prove its existence by pasting a paper label on the bottom

[1] A Paper read by Thomas Fletcher, F.C.S., at the Gas Institute Meeting, London, June 9.

of one of the boilers, and exposing this to the direct impact of a powerful burner during the time the water is being boiled, and you will see that it comes out perfectly clean and uncoloured. Now it is well known that paper becomes charred at a temperature of about 400° F., and the fact that my test-paper is not charred proves that it has not been exposed to this temperature, the flame being, in fact, extinguished by the cooling power of the water in the vessel. I need hardly remind you that the speed with which convected or conducted heat is absorbed by any body is in direct ratio to the difference between its own temperature and that of the source of heat in absolute contact with it; and therefore, as the source of the heat taken up by the vessel is nothing but unburnt gases, at a temperature below 400° F., the rate of absorption cannot, under any circumstances, be great, and the usual practice is to compensate for this inefficiency by an enormous extension of surface in contact with the water, which extension I will prove to you is quite unnecessary. You will see I have here a copper vessel with a number of solid copper rods depending from the lower surface; each rod passes through into the water space and is flattened into a broad head, which gives up its heat rapidly to the water. My theory can be stated in a few words: The lower ends of the rods, not being in close communication with the water, can, and do attain, a temperature sufficiently high to admit of direct flame contact, and as their efficiency, like that of the water surface, depends on the difference between their own temperature and that of the source of heat in absolute contact with them, we must, if my theory is correct, obtain a far greater duty from them. I do not wish you to take anything for granted, and although the surface of the rods, being vertical, can only be calculated for evaporating power at one-half that of a horizontal surface, as is usual in boiler practice, my margin of increased duty is so great that I can afford to ignore this, and to take the whole at what its value would be as horizontal surface, and still obtain a duty 50 per cent. greater from a surface which is the same in area as the flat-bottomed vessel on the fire side, but having only one-third the surface area in contact with the water. I do not, of course, profess to obtain more heat from the fuel than it contains, but simply to utilise that heat to the fullest possible extent by the use of heating surfaces, beyond comparison smaller than what have been considered necessary, and to prove not only that the heating surfaces can be concentrated in a very small area, but also that its efficiency can be greatly increased by preventing close water contact, and so permitting combustion in complete contact with a part of the heating surface. I will now boil 40 ounces of water in this flat-bottomed copper vessel, and, as you will see, sharp boiling begins in 3 minutes 15 seconds from the time the gas is lighted. The small quantity of steam evolved before this time is of no importance, being caused partly by the air driven off from the water and partly from local boiling at the edges of the vessel owing to imperfect circulation. On the bottom of this vessel is pasted a paper label which you will see is untouched by the flame owing to the fact that no flame can exist in contact with a cold surface.

It may be thought that, owing to the rapid conducting power of copper, the paper cannot get hot enough to char. This is quite a mistake, as I will show you by a very curious experiment. I will hold a small plate of copper in the flame for a few seconds, and will then hold it against the paper. You will see that, although the copper must of necessity be at a temperature not exceeding that of the flame, it readily chars the paper. We can, by a modification of this experiment, measure the depth of the flameless space, as the copper, if placed against the paper before it has time to be previously heated, will, if not thicker than 1/40 inch, never become hot enough to discolour the paper, showing that the flame and source of heat must be below the level of a plate of metal this thickness.

In repeating this experiment I must caution you to use flour paste, not gum, which is liable to swell and force the paper past the limit of the flameless space, and also to allow the paste to dry before applying the flame, as the steam formed by the wet paste is liable also to lift the paper away and force it into the flame. I will now take this vessel, which has only one-half the surface in contact with the water, the lower half being covered with copper rods, 3/16 inch diameter, ½-inch centres apart, and 1½ inch long, and you will see that with the same burner as before, under precisely the same conditions, sharp boiling takes place in 1 minute 50 seconds, being only 13 seconds more than half the time required to produce the same result with the same quantity of water as in the previous experiment. Although the water surface in contact with the source of heat is only one-half that of the first vessel, and the burner is the same, we can see the difference not only in the time required to boil the 40 ounces of water, but also in the much greater force and volume of steam evolved when boiling does occur. With reference to the form and proportions of the conducting rods, these can only be obtained by direct experiment in each case for each distinct purpose. The conducting power of a metallic rod is limited, and the higher the temperature of the source of heat, the shorter will the rods need to be, so as to insure the free ends being below a red heat, and so prevent oxidation and wasting. There are also other reasons which limit the proportions of the rods, such as liability to choke with dirt and difficulty of cleaning, and also risk of mechanical injury in such cases as ordinary kettles or pans; all these requirements need to be met by different forms and strengths of rods to insure permanent service, and, as you will see further on, by substituting in some cases a different form and type of heat conductor. To prove my theory as to the greater efficiency of the surface of the rods in contact with the flame as against that in direct contact with the water, I have another smaller vessel which, including the rods, has the same total surface in contact with the flame, but only one-third the water surface as compared with the first experiment. Using again the same quantity of water and the same burner we get sharp boiling in 2 minutes 10 seconds, being an increase of duty of 50 per cent., with the same surface exposed to the flame. The rods in the last experiment form two-thirds of the total heating surface, and if we take, as I think for some careful experiments we may safely do, one-half the length of the rods to be at a temperature which will admit of direct flame contact, we have here the extraordinary result that flame contact with one-third of the heating surface increases the total fuel duty on a limited area 50 per cent. This really means that the area in contact with flame is something like six times as efficient as the other. In laboratory experiments it is necessary not only to get your result, but to prove your result is correct, and the proof of the theory admits of ready demonstration in your own laboratories, although it is unfit for a lecture experiment, at all events in the only form I have tested it. If you will take two ordinary metal ladles for melting lead, cover the lower part of one of these with the projecting rods or studs and leave the other plain, you will find on melting a specified quantity of metal in each that the difference in duty between the two is very small. The slight increase may be fully accounted for by the difference in the available heating surface reducing the amount of waste heat passing away, and this proves that flame-contact, and therefore quick absorption of heat, takes place on plain surfaces as soon as these are above a certain temperature, which, in a metal ladle, very soon occurs. What the temperature is which admits of flame-contact I have, as yet, not been able to test thoroughly, and it will need some consideration how the determination of this is to be correctly made; at the same time it is a question in physics which should be capable of being answered.

Let us now take the other side of the question. If the efficiency of a surface depends on flame contact, there must of course be flame, or at least gases of an extremely high temperature, and we therefore cannot expect this extraordinary increase of efficiency in any part of our boiler except where flame exists, and if these projectors are placed in a boiler, anywhere except in contact with flame, their efficiency must be reduced to that of ordinary heating surface. They are, of course, useful, but only in the same way as ordinary flue surface. When we come to boilers for raising steam, which have to stand high pressures, we come to other difficulties of a very serious nature, which require special provision to overcome them. To put such rods as I have referred to in a boiler-plate necessitates the plate being drilled all over with holes, causing a dangerous source of weakness, as the rods cannot be used as stays; further than this, they would render really efficient examination a matter of extreme difficulty, and would be liable to give rise to frequent and almost incurable leakages; but there is, fortunately, a very simple way to overcome this difficulty. I have found that rods or points, such as I have described, are not necessary, and that the same results can be obtained by webs or angle-ribs rolled in the plates. My experiments in this direction are not complete, and at present they tend to the conclusion that circular webs, which would be of the greatest efficiency in strengthening the flues, are not so efficient for heating as webs running lengthwise with the flue, and in a line with the direction of the flame. This point is one which I am at present engaged in testing with experimental

boilers of the Cornish and Lancashire types, and as, with gas, we have a fuel which renders every assistance to the experimenter, it will not take long to prove the comparative results obtained by the two different forms of web. Those of you who have steam-boilers will, no doubt, know the great liability to cracking at the rivet-holes in those parts where the plates are double. This cracking, so far as my own limited experience goes, being usually, if not always, on the fire side, where the end of the plate is not in direct contact with the water—where it is, in fact, under the conditions of one of the proposed webs —I think we may safely come to the conclusion that this cracking is caused by the great comparative expansion and contraction of the edge of the plate in contact with the fire; and it will probably be found that if the plates are covered with webs the whole of the surface of the plates will be kept at a higher and more uniform temperature, and the tendency to cracks at the rivet-holes will be reduced. This is a question not entirely of theory, but needs to be tested in actual practice.

There is another point of importance in boilers of the locomotive class, and those in which a very high temperature is kept in the fire-box, and this is the necessity of determining by direct experiment the speed with which heat can safely be conducted to the water without causing the evolution of steam to be so rapid as to prevent the water remaining in contact with the plates, and also whether the steam will or will not carry mechanically with it so much water as to make it objectionably wet, and cause priming and loss of work by water being carried into the cylinders. I have observed in the open boilers I use that when sufficient heat is applied to evaporate 1 cubic foot of water per hour from 1 square foot of boiler surface, the bulk of the water in the vessel is about doubled, and that the water holds permanently in suspension a bulk of steam equal to itself. I have, as yet, not had sufficient experience to say anything positively as to the formation or adhesion of scale on such surfaces as I refer to, but the whole of my experimental boilers have up to the present remained bright and clean on the water surface, being distinctly cleaner than the boiler used with ordinary flat surfaces. It is, I believe, generally acknowledged that quick heating and rapid circulation prevents to some extent the formation of hard scale, and this is in perfect accord with the results of my experiments. The experiments which I have shown you I think demonstrate beyond all question that the steaming-power of boilers in limited spaces, such as our sea-going ships, can be greatly increased; and when we consider how valuable space is on board ship, the matter is one worthy of serious study and experiment. It may be well to mention that some applications of this theory are already patented.

I will now show you as a matter of interest in the application of coal gas as a fuel how quickly a small quantity of water can be boiled by a kettle constructed on the principle I have described, and to make the experiment a practical one I will use a heavy and strongly-made copper kettle which weighs 6½ lbs., and will hold when full one gallon. In this kettle I will boil a pint of water, and, as you see, rapid boiling takes place in 50 seconds. The same result could be attained in a light and specially-made kettle in 30 seconds, but the experiment would not be a fair practical one, as the vessel used would not be fit for hard daily service, and I have therefore limited myself to what can be done in actual daily work rather than laboratory results, which, however interesting they may be, would not be a fair example of the apparatus in actual use at present.

THE CRATERS OF MOKUAWEOWEO, ON MAUNA LOA[1]

DURING last year I was engaged for many months in surveying lands on Mauna Hualalai and Mauna Loa, in Hawaii, and in that way had an opportunity of making investigations of craters and lava flows that may be of interest to those studying volcanic phenomena.

It would seem that, as the best histories are those written long after the events which they record, when all the reports of eyewitnesses can be carefully examined, so the best descriptions of volcanic action may be obtained long after eruptions, by carefully investigating the records indelibly inscribed in the rocks.

The ascent of Mauna Loa is so seldom made that a brief account of my excursions may be interesting.

[1] By J. M. Alexander, from the *Hawaiian Commercial Advertiser* of October 1885.

On September 1, 1885, I set out in company with Mr. J. S. Emerson, of the Hawaiian Government Survey, to ascend that mountain from the table land east of Hualalai, along the south side of the lava-flow of 1859, which, as many will remember, was visited by a party from Oahu College. We were provided with mules for riding and pack-donkeys, and accompanied by several natives, including a so called guide, who lost himself and delayed us over a day in searching for him.

Our route led first through a narrow belt of forest, consisting of mamane, ohia, and sandalwood trees; then through a scanty vegetation of ohelos and the beautiful *Cyathodes Tameiameiæ*, and at last beyond the limits of vegetation, without a vestige even of moss or lichen, over a wonderful and awful billowy waste of "pahoehoe" lava, traversed by tracts of "aa" and deep chasms.

At about two-thirds of the distance towards the summit we passed the rugged crater hill from which the outbreak of 1859 had issued, and here our path was strewed with pumice and "Pele's hair" from that eruption. There was an enormous quantity of lava poured forth from the small fissure of this crater, forming a stream from half a mile to two miles wide, and reaching nearly thirty miles to the ocean at Kiholo. Lower down I counted eighteen species of ferns and a dozen kinds of phenogamous plants already growing on this flow. In this vicinity the caverns contained many carcasses of wild goats. In one further south I counted eighty of their skeletons and decaying bodies. They had probably leaped in for shelter, and had been unable to leap out.

When near the summit our guide warned us to descend, because of an approaching storm; but Mr. Emerson and I, anxious to accomplish the object of our journey, set out without him through the driving rain that soon turned into hail and then into snow, marking our route with flags so that we might be able to find our way back. In a short time we reached the brink of the vast crater of Mokuaweoweo, filled with fog and surrounded by frightful precipices. Along this brink were numerous deep fissures filled with ice and water, the beginning of cleavage for avalanches into the crater. Here, and for a quarter of a mile below, we observed many rocks of a different kind from the surface lavas, solid, flinty fragments of the foundation walls, weighing from fifty pounds to a ton, which had formerly fallen down upon the crater floor and had afterwards been hurled out during eruptions. I noticed similar rocks around the summit craters of Hualalai. It would be unsafe to approach the crater at this place during eruptions, when such brickbats were flying.

We returned to our camp about noon, and sent the poor animals, which had stood all night in the icy wind tied to jagged rocks, in the care of the guide down the mountain; and with the help of one native, with much difficulty, carried a tent and supplies to the summit.

At evening the fog lifted and gave us a glimpse of the craters. Immediately below us lay the central crater, surrounded by almost perpendicular walls, with a pahoehoe floor streaked with grey sulphur cracks, from hundreds of which there issued columns of steam, and with a still smoking cone in the south end. Beyond this central crater on the south rose a high plateau, and beyond this plateau still further south we saw an opening into another crater small and deep. In the opposite direction, north of the central crater, appeared another higher crater like an upper plateau, from which a torrent of lava had once poured into the central crater, and north of this again another crater, like a still higher plateau, from which also lava had flowed south.

Thus it was evident, as appeared more clearly by subsequent investigation, that Mokuaweoweo is not simply one crater, but a series of four or five craters, the walls of which have broken down, so that they have flowed into each other.

The crater of Haleakala, on Maui, was probably formed in a similar manner out of several ancient craters which have broken into each other. These vast chasms may well be called calderas, as has been recommended by Captain Dutton. On Hualalai there is a series of craters having the same relative position as those of Mokuaweoweo, and crowded so close together as to be almost broken into one. On the older mountains, like that of West Maui, such congeries of craters have evidently formed the starting-points for deep valleys, which the rain torrents, leaping down their lofty walls, have torn out through concentric layers of lava to the sea. Just before sunset we saw the splendid phenomenon of the "Spectre of the Brocken" (Hookuaka),

our shadows on the mist, encircl . with rainbows, over the black inferno.

We erected a survey signal for determining the location and height of the summit, and also of an important land boundary in the crater, viz. the corner where the four lands of Keauhou, Kahuku, Kapapala, and Kaohe meet, which is at the cone in the central crater. We then descended the mountain, carrying more weight than was agreeable, until we were met by our natives bringing up our mules, for which we had signalled by fires. On the way down a violent thunderstorm was raging below us, while we were above in clear air. On my next trip up this mountain I found a tree on the slope below completely rent to splinters, and parts of it thrown several rods, by the lightning of this storm.

During the next month I ascended the mountain again, this time carrying an excellent engineer's transit. As I had no guide, I marked most of the way up by strips of cloth fastened to rocks to find the way back; and taught by our former experience, I took a donkey-load of fuel, as well as a load of grass for making a spherical survey signal, which served me several nights as a bed. When about half-way up the mountain, one of our pack-donkeys broke into a lava cave, and slid downwards nearly out of sight. It was extricated with great difficulty by a direct upward lift with ropes. I then sent one of my men down the mountain with the donkeys, retaining the other man with me. The first night on the summit was uncomfortable enough for us, with a storm from the north. At midnight we observed with a lighted candle that the roof of the tent was a-sparkle with icicles, and on touching it found it frozen stiff as a bullock's hide. In the morning we found a beautiful sheet of snow an inch thick over the tent and over all the ghastly blackness of the rocks. Every morning of our stay upon the mountain we found the water frozen in our kettles, and hoar-frost on the rocks.

In the clear frosty air I was able with my transit to take the bearings of a dozen survey signals on the slopes and summit of Hualalai.

The new spherical signal which I had erected was afterwards accurately determined by observations from more than twenty stations on Mauna Kea, Hualalai, and in South Kona, and thus a trigonometrical station was at last located on the very summit of Mauna Loa.

On the second day I descended from the west brink of the crater down the track of a high avalanche of rocks upon the second plateau, and again from this plateau by the path of another avalanche into the central crater, stepping cautiously down upon the black floor of the crater, lest it should break under our weight. We found this caution unnecessary, for much of the crater bottom proved to be the most solid kind of pahoehoe.

Here we stood as on the congealed surface of a tossing sea that had dashed its fiery surf thirty feet up on the surrounding walls. We travelled directly south for the cone, the boundary corner, which I was to locate, erecting two flags about 2500 feet apart for the ends of our base-line. In some places, where there appeared to have been violent action, the lava broke under our feet, letting us down into caverns. In some large tracts the pahoehoe was covered with pumice, indicating the violence of the former surging and tossing of the lava, for pumice and other light lavas seem to be the froth and foam of the fiercest eruptions. Just before reaching the cone we came to a deeper basin, twenty or more feet below the rest of the crater bottom and about 400 feet wide, covered with the most friable lava, swollen upwards as though raised by air-bubbles, and this basin extended in a lava flow to the north-east along the side of the crater.

Probably this was the place of the last eruption, and of most of the eruptions of this central crater. We found the cone to be composed of pumice and friable lava still hot and smoking, and very difficult to ascend, but we succeeded in climbing to its top, 140 feet high, and in setting up a flag there for the boundary corner. We then descended between the east and west peaks of this cone over huge rocks and deep chasms.

From the fact that this cone is represented on Mr. J. M. Lydgate's map of 1874, I conclude that it has been of long continuance, probably composed of the cinders of successive eruptions, and that the deep basin to the windward of it, like Halemaumau in Kilauea, has continued many years, and is situated at the great central volcanic throat of the mountain.

I then returned to the second plateau to the north, and thence clambered out to the east of Mokuaweoweo by the extremely interesting route of a former cataract of lava from the summit into the crater, the swift downfall of which had turned its lava almost into pumice, and the black, shining spray of which lay spattered on the surrounding rocks.

Further south I observed the course of two other cataracts, which had poured directly into the central crater. At the summit I found the deep fissure from which the outbreak had come that caused these cataracts, and ascertained that it had also poured an immense stream north upon the first plateau and thence south to the central crater. Crossing from this place to the north over the first plateau I suddenly came to a frightful circular crater in the bed of the plateau, apparently 600 feet deep and 1000 feet wide, with a cone in its centre still smoking. We were obliged to hurry with exhausting speed over rough lava in order to reach our tent before night.

The next day we took the transit to the stations in the crater, and the next we surveyed with it along the western brink to the extreme south end, where we looked down into the south crater, which is about 800 feet deep and 2500 feet wide. The length of the whole chasm, or "caldera," I have ascertained to be about 10,000 feet, the greatest breadth 9000 feet, and the greatest depth 800 feet. The area is three and six-tenths square miles. A map of these craters has been sent to the Government Survey Office.

On the south-west side, near the junction of the central crater with the south plateau, I found that there had been another eruption, from fissures that were still smoking, and that this eruption had poured an immense stream southward towards Kahuku, and had also poured cataracts into the south crater from all sides.

I had everywhere observed that there had been great flows from the summit brink down the mountain, and had wondered at the thought of the vast chasm having filled up and overflowed its brim.

This, however, turned out to be an incorrect view. The flows have not been from the lowest parts of the brim, but from some of the highest, which could not have been the case in an overflow.

The walls of the craters are largely composed of loose, old, weather-beaten rocks, and large tracts of the plateau are composed of old pahoehoe that has not been overflowed for ages, which would not be the case if the craters filled and overflowed.

These outbreaks from fissures around the rim indicate that the lava has rather poured into the crater than out of it; and that it has poured from such fissures in vast streams down the mountain-side. What enormous quantities of lava may flow from such small fissures is illustrated by the flow of 1859. The question arises, How has the lava risen high enough to pour in extensive eruptions through these fissures, almost a thousand feet above the bottom of the crater, without rising in the crater and overflowing it? The same question has often been asked in respect to the rise of liquid lava to the summit of Mauna Loa without overflowing the open crater of Kilauea, 10,000 feet below.

We have seen that it is not because the lava in Mokuaweoweo is lighter than that in Kilauea that it rises so much higher. In fact, it is as solid there as in Kilauea. The explanation has occurred to me that molten lavas rise the higher the smaller the conduits in which they rise from their subterranean reservoirs.

An illustration is afforded by the "spouting horns" on the sea-coast, where the ocean, rushing into caverns of rock, drives columns of water through small openings to the height of forty or fifty feet above high-water mark. We see another illustration in water conveyed in pipes, which jets the higher the smaller the orifice.

However violent the subterranean pressure may be, Kilauea does not overflow, but only rages the more fiercely, because its passage from the chambers below is so large. But through the vast mountain of Mauna Loa there is no doubt a constricted conduit leading upward; and there must be still smaller conduits to the fissures on the summit rim. On this theory, the molten lava rises higher through Mauna Loa than in Kilauea, because Mauna Loa has the smaller throat.

It is therefore by no means certain that there is no subterranean connection between the two volcanoes.

Another vexed question, of which several solutions have been proposed, is the mode of formation of the two strongly contrasted forms of lava known as "pahoehoe" and "aa." The former term is applied to tracts of comparatively smooth and uniform lava, as though it had cooled while flowing quietly; the latter to tracts of broken lava, as though it had cooled when tossing like an ocean in a storm, and had then been broken up by earth-

quakes. As Mr. Brigham states, "No words can convey an idea of its horrible roughness and hardness."

My own belief is that "aa" has been formed simply by obstructions breaking the quiet flow of molten lava. Every observer has noticed that "pahoehoe" contains ducts and air-chambers, having an upper crust contorted into the shape of the waves and ripples of the flowing lava. The liquid lava has evidently flowed in these ducts and chambers, and at last flowing out has left them empty with glazed interior surfaces. In like manner torrents of lava have poured through caverns down the mountains to the sea, and flowing out have left the innumerable caves, smooth and shining within, to be found all over the island. Now, when there are obstructions on the earth's surface or meeting flows, this system of ducts is broken up, and fragments of lava are carried along on the surface, piling up higher than the adjacent "pahoehoe," like ice-packs in rivers, and sometimes rolling immense boulders twenty and thirty feet high, which now stand on the "aa" with the drip glistening over them. This theory is confirmed by the fact that "aa" is always higher than the adjoining "pahoehoe," and also by the fact, which I especially noticed in the flow of 1859, that wherever there are open spaces in lava flows (kipukas), the old lava under the flow is found to be "pahoehoe" under "pahoehoe" and "aa" under "aa."

While surveying the region I was extremely interested in the arrangement of the craters; and now having determined the situation of more than fifty of them on Mauna Loa, Hualalai, and Mauna Kea, I have ascertained that there is a method in their arrangement. They are not arranged relatively to the mountain on which they are situated, but relatively to the points of the compass. There seems to have been a series of nearly parallel fissures through which these craters have risen, in lines running from S. 40° E. to S. 60° E. There are a few arranged in lines running N. 50° E.

It has been remarked by Mr. W. T. Brigham that, while the general trend of the Hawaiian group and of the major axis of each island is N. 60° W., there is no crater on the islands whose major axis is parallel to this line. "On the contrary," he continues, "a very interesting parallelism is observed among all the craters, and invariably the longest diameter is north and south." It would be more correct to say that the major axes of the great craters are generally at right angles to the general axis of the group, *i.e.* about N. 30° E. Haleakala and the ancient Kipahulu caldera appear to take the other direction, but the statement is certainly true of the great calderas of Kilauea and Mokuaweoweo, which have other points of resemblance.

Thus in both the highest walls are on the western side, and in both the action is working towards the south-west, as is indicated by the fact that the north-east craters are nearly filled up, while the deepest and active craters are in the south-west end of the caldera.

It has been shown by Prof. Dana and other geologists that the principal mountain-ranges of the globe, as well as the main coast-lines and chains of islands, take the two directions just mentioned, "which are in general tangential to the Arctic and Antarctic circles." Thus it appears that the laws in accordance with which the volcanic forces are now operating in these islands are the same as those by which all the grand features of our world have been established, and possibly related to the laws of crystallisation which pervade the mineral kingdom; and thus we perceive a unity in the processes of the globe.

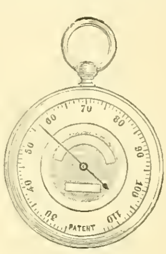
In conclusion, I would remark that to my mind the most plausible theory to account for volcanic action is that of Mallet, that the contraction of the earth's crust continually going on under the power of gravitation causes as much internal heat as would be required to cause a similar expansion. Prof. Dana has remarked that "the fact is well established that motion in the earth's rocks has been a powerful source of heat," and that the annual crushing of not over one-sixth of a cubic mile of rocks in the earth would cause all the volcanic phenomena of the world. This theory has the beauty of attributing all these phenomena to a single cause, and of thus suggesting the thought of the one great Power above the inexplicable forces of gravitation, who continues all the forces of the universe.

IMMISCH'S THERMOMETER

THIS instrument depends for its action upon the opening and closing of a minute volute Bourdon tube, which for this purpose is filled with expansive liquid and hermetically sealed. One end of the tube is fixed, and the free end is brought into contact with the short arm of a lever, the long arm of which forms a rack gearing with a pinion which carries the pointer. The position of the tube with regard to the short lever-arm is such that for ordinary purposes the divisions on the dial are equal, while for clinical use the scale is an increasing one, in order that near blood-heat the divisions become wider to permi of a fraction of a degree being read off accurately.

The success which these instruments meet with is owing principally to their sensitiveness, accuracy, and non-liability to get broken. If they should meet with an accident they can be easily repaired.

The appellation "metallic" does not seem to be a happy one for these thermometers, as they are likely to be confounded with the unsuccessful attempts which have been made to produce instruments for similar purposes by means of bi-metallic laminæ. The defects of the latter are the extremely small *vis viva* avail-



able for the work of multiplying the small motion of the laminæ, and the liability to not return to precisely the same point after being subjected to extremes of temperature. In this latter respect there is a double security with the instrument which is the subject of this notice. The tube is in itself a very flexible spring, the motion of which does not overreach the limits of perfect elasticity, and its position at any given time is determined by the volume of the liquid, which, of course, remains always a constant quantity whatever the volume may be. As the tube is absolutely full, it must of necessity always accommodate itself to the volume and correctly indicate the temperature.

As regards accuracy, we are informed that upwards of 500 have already been tested at Kew—we have ourselves seen the certificates of the last group of two dozen clinical ones, and they give the remarkable results of perfect accuracy at 66 per cent. of the points tested, and of no error greater than $0°{\cdot}2$ at any point on any one of the twenty-four thermometers.

SCIENTIFIC SERIALS

Rendiconti del Reale Istituto Lombardo, May 13.—On the theory of waves, by Prof. E. Beltrami. The author presents some considerations which place in a clearer light the process by which F. Neumann deduces the laws of Fresnel from the fundamental equations of elasticity.—Dynamics of moving systems which preserve their mutual affinity, by Prof. C. Formenti.

Rivista Scientifico-Industriale, May 31.—Maximum and relative humidity of the atmosphere, by Prof. Paolo Cantoni. Hygrometric tables of mean annual moisture, recorded at thirty meteorological stations in various parts of Italy, show that the average of maximum and relative humidity increases from north to south, from elevated to low-lying stations, and from inland to maritime districts.—On the persistence of the mathematical figure of the earth throughout the geological epochs, and on the constitution of the terrestrial crust, by Prof. Annibale Riccò. A summary is given of M. H. Faye's views on this subject already published in the *Comptes rendus* of the French Academy (March 22 and April 5, 1886), the author concluding that the mathematical figure of the globe, as represented by the surface of oceans, has not been perceptibly modified by the geological forces associated with the cooling process.—On the permanent magnetism of steel at various temperatures, by Prof. Poloni. It is shown that at the temperature of 180° C. the well-known law of magnetic distribution in steel bars no longer holds good when

the bars have been magnetised without being first subjected to great variations of temperature and kept free from telluric action by being held in a vertical position.

SOCIETIES AND ACADEMIES

LONDON

Royal Microscopical Society, June 9.—Rev. Dr. Dallinger, F.R.S., President, in the chair.—Mr. G. F. Dowdeswell described a preparation of the microbe of rabies in the spinal cord of a rabid dog, which he exhibited × 400. — Prof. F. Jeffrey Bell exhibited a specimen (received from Prof. McIntosh) of a very young starfish, in a stage so early as to show clearly the knob-like portions of the larval organ. Prof. McIntosh has been giving some of his knowledge and skill to fishing observations, which had been rendered possible by the facilities afforded by an enlightened Fishery Board in Scotland.—Mr. F. R. Cheshire exhibited a device for the better examination of Bacteria in culture tubes, the cylindrical form of the tube so distorting the appearance of the contents that it was almost impossible to make any observations upon them under the microscope. The first plan adopted was that of placing the tube in a trough of water and then looking at it through the front of the trough. This was found to diminish the aberration very much, but it did not get rid of it altogether, and was, therefore, only available under very low powers. Water having a refractive index of about 1·333 and alcohol of about 1·374, by adding water to alcohol a mixture having a refractive index of anything between the two could be obtained according to the proportions used. Gelatine has a refractive index rather higher than that of water, and the interposition of a cylinder of glass added something to this. The trough which he employed had a front of rather thin glass, the bottom being sloped in such a way as to cause a tube placed in the trough to lie always near to the front. The tube to be examined was placed in the trough with some water, and then alcohol was added until the proper density was arrived at, and by this means it was quite possible to use a $\frac{1}{8}$-inch objective effectively.—Prof. Bell, at the request of the President, gave an account of what he regarded as the most extraordinary biological fact brought to light during the last twenty-five years—that of a third eye at the top of the head of certain lizards.—Mr. Crisp called attention to a new lamp for the microscope which had been sent for exhibition by Mr. Curtis, and which was so cheap and simple that it seemed likely to become the lamp of the future. It was founded on the lamp originally devised by Mr. Nelson.—Mr. A. Brachet's communication suggesting the use of a hyperbolic lens for the field-lens of the eye-piece was read. Mr. Brachet claimed that thereby the diaphragms in the eye-piece and objective could be dispensed with, and the image much improved.—Dr. Crookshank read a paper on photo-micrography, which was illustrated by the exhibition of a large number of prints, negatives, &c. Mr. Glaisher, President of the Photographic Society, said he had examined Dr. Crookshank's exhibits, and thought they were certainly very beautiful productions. He had for many years taken a great interest in the subject of photography, and had looked to it with hopes which had been more nearly fulfilled than ever before by the specimens before them. He had heard the paper with great pleasure, and could only express his admiration of it, believing as he did that it held out great promise for the future.—Mr. F. Enock exhibited sketches of some of his slides, the various parts being numbered and named and accompanied by a short explanation. It is intended to issue sketches of all the mouth organs of British bees and other interesting insects.

Mineralogical Society, June 22.—Mr. L. Fletcher, President, in the chair.—Mr. Andrew Taylor was elected a Member.—The following papers were read:—C. O. Trechmaine, Ph.D., on barytes from Addiewell, West Calder, N.B.—Prof. E. Kinch, on plattnerite.—F. H. Butler, M.A., on dufrénite.—R. H. Solly, on anglesite from Portugal; and on apatite from Cornwall.—Mr. R. Simpson (visitor) exhibited a very large rolled crystal topaz from Tasmania.—Several interesting specimens were re-exhibited by the President, Mr. Rudler, and others.

PARIS

Academy of Sciences, June 28.—M. Jurien de la Gravière, President, in the chair.—On the theory of minima surfaces, by M. G. Darboux. The results hitherto arrived at in the study of minima surfaces lead naturally to the inquiry here instituted regarding the determination of all minima algebraic surfaces contained in a given algebraic curve, or, more generally, to determine all the minima algebraic surfaces inscribed in a given algebraic curve.—On the subject of certain circumstances presented by the movement of the hydro-extractor, by M. de Jonquières. The author deals with the normal case (omitted by Poinsot), in which the movement of precession is complicated and rendered irregular by movements of nutation.—On a process by means of which the oscillations of an absolutely free pendulum may be mechanically counted, by M. M. Deprez. The principle is described of an apparatus not yet constructed, which is intended to record the number of vibrations without exercising any mechanical influence on the pendulum. Without this condition the results would be worthless, as the vibrations, instead of being effected under the influence of gravitation alone, would be affected by the action of a force of unknown magnitude. The problem is solved by the aid of optics, light being the only agent which exercises no mechanical action on the bodies exposed to its influence.—On the persistence of voluntary movements in bony fishes after removal of the cerebral lobes, by M. Vulpian. The author's experiments with carp fully confirm Steiner's recent conclusions regarding the persistence of the voluntary movements in fishes thus operated upon. They also show that the faculty of sight is unaffected by the operation, as already proved by the author in 1864.—On the normal metronome, by M. Saint-Saens. Owing to the defective character of this instrument, it is found to be of little practical service to musicians. Hence the Academy is urged to supply a normal metronome mathematically regulated which, before being issued to the public, should be tested and stamped like all diapasons, weights, and measures. The matter was referred by the President to the Section for Mechanics and Physics.—On the extension of a theorem of Clebsch relating to curves of the fourth degree, by Prof. Sylvester.—A fresh series of experiments on the automatic action of the regulating apparatus constructed at the Aubois sluice, by M. A. de Caligny.—On the fluorescence formerly attributed to yttria, by M. Lecoq de Boisbaudran. By recognising the complex character of yttria and announcing the existence of new elements characterised by fluorescent bands at first attributed to yttria (NATURE, June 17, pp. 160–62), the author considers that Mr. Crookes has implicitly adopted the opinion always held by him regarding the true character of these bands. But from the fresh experiments here described it is pointed out that further interesting studies will have to be made in order thoroughly to elucidate the subject.—Remarks accompanying the presentation of a work entitled "Cosmogonic Hypotheses: an Inquiry into the Modern Scientific Theories on the Origin of Worlds, with a Translation of Kant's 'Theory of the Heavens,'" by M. Wolf. In writing this work the author's object has been to show that the theory of Laplace, completed by the labours of M. Roche and other *savants*, still answers best to the conditions required of a cosmogonic hypothesis. He claims to have met all the objections urged against it, and especially that of M. Faye regarding the pretended necessity of a retrograde rotation of the planets.—Report on M. Poincaré's memoir entitled "Influence of the Moon and Sun on the Northern Trade-Winds," by the Commissioners, MM. d'Abbadie and Mascart. With certain reservations this memoir is recommended to the favourable consideration of the Academy. It shows that there is some truth in the popular opinion respecting the influence of the moon on the weather, but that this influence should be referred not to the new, but to the waning phases of the moon, while account should also be taken of the antagonistic influence of the sun.—Action of an electric current on anhydrous hydrofluoric acid, by M. H. Moissan.—On the flow of gases in the case of a permanent *régime*, by M. Hugoniot. It is shown that M. Hirn's experiments in no way contradict either the kinetic theory or the laws of hydrodynamics, and, so far from refuting, actually confirm the well-known formula of Weisbach or Zeuner.—On the condensation of vapours, by M. P. Duhem.—On the coefficient of self-induction in the Gramme machine (three illustrations), by M. Ledeboer.—On the spectra of didymium and samarium, by M. Eug. Demarçay. Some fresh results are described, which the author has obtained from the study of the photographed absorption-spectra of various products of the fractionation of didymium and samarium.—On a new double iodide of copper and ammonia, by M. A. Saglier. The process is explained by which the author has obtained this

new compound, whose formula is $2NH_3Cu_2I_2$, as shown by the following figures :—

	Found			Theory
Copper	24·66	24·61	...	24·84
Iodine	66·03	65·91	...	66·27
Ammonia	8·58	8·66	...	8·88

—On the synthesis of an inactive terpilenol, by MM. G. Bouchardat and J. Lafont.—Action of anhydrous baryta on methylic alcohol, by M. de Forcrand. From the author's experiments it follows that whenever the solution of baryta takes place in methylic alcohol in the presence of a trace of water, which it is very difficult to avoid, the resulting compound should be $C_2H_4O_2,BaO,H_2O_2$.—Action of heat on the acetones, by MM. P. Barbier and L. Roux. The paper deals fully with the mode of decomposition which these substances undergo when subjected to the influence of red heat.—Decomposition of pilocarpine, by MM. E. Hardy and G. Calmels.—Researches on the development of beetroot, by M. Aimé Girard. Here the author studies more especially the tap-root and radicules, concluding that the saccharine matter is formed, not in the underground, but exclusively in the overground parts of the plant.—On the functions of the ovoid gland, of Tiedemann's bodies, and Poli's vesicles in the Asteridæ, by M. Cuénot.—On the conjunctions of the ciliated Infusoria (*Colpidium colpoda*, *Paramecium aurelia*, and *Euplo'es patella*), by M. E. Maupas.—On the classification of the Thaliaceæ and some other groups of Ascidians, by M. F. Lahille.—Note on the *Amphistegina* of Porto Grande, St. Vincent Island, by M. de Folin.—On the functions of the cephalic fossettes in the Nemertæ, by M. Remy Saint-Loup.—Researches relative to the influence of the nerves on the production of lymph, by M. Serge Lewachew.—On the anatomic constitution of the Ascidians attached to the rare American plant *Heliamphora nutans*, Benth., By M. Ed. Heckel.—On the presence of a line of erratic boulders stranded on the coast of Normandy, by M. Ch. Vélain.—On the eruption of Etna during the months of May and June, by M. H. Silvestri. The discharge during twenty days of activity has been approximately estimated at 66,000,000 cubic metres.

BERLIN

Physiological Society, May 28.—Dr. Virchow made a report of his investigations into the capillaries of the vitreous body and their environment. The vitreous body, which must no longer be regarded as a tissue, but as an organ, showed different structural relations among the different groups of animals, and, in the case of fishes and the frog, was distinguished by its strong bounding cuticle, on which the capillaries formed an object of interesting examination. In regard to the structure of the capillaries the speaker had come to the conviction that they consisted of a fundamental membrane which was occupied with cells. The environment of the capillaries formed lymph-spaces, which had not yet, however, manifested themselves as standing in continuous connection with one another. On the cuticles inclosing the lymph-spaces lay cells displaying a great multiplicity in form and arrangement among the different kinds that had been examined.—Prof. Munk attacked the position taken up at the last sitting of the Society by Prof. Christiani respecting the possibility of seeing after excision of the greater brain. He challenged his opponent to show to the Society or the Association of Naturalists for this year a rabbit that was able to see after the removal of the greater brain.—Dr. Benda exhibited a series of preparations of the central nervous system which were coloured in accordance with the hæmatoxyline method as modified by him. There were in particular three advantages distinguishing his hæmatoxyline colouring from that of Weigert's: (1) the axial cylinders of the nerve fibres in the brain came out more distinctly, and their connection with the ganglia cells was directly demonstrated. (2) The structure of the ganglia came out more distinctly. In the case of those ganglia which remained clear after the hæmatoxyline colouring, there appeared with great constancy in the fibrous framework, dark concretions, which might perhaps be interpreted as a special structure, though the speaker was not yet prepared to decisively maintain that assumption as fact. (3) With still more reservation would he present the third result, which came to light in a particular structure of the medullary sheath. On the transverse section radiate drawings were seen to proceed from the axis cylinder towards the neurilemma. These markings ramified, and perhaps formed the protoplasmatic scaffold within which was deposited the fluid nerve-medulla. The speaker next described more minutely his method of proceeding—hardening with picrin acid, washing out with alcohol, laying in paraffin, treating with a sulphate of iron, colouring with hæmatoxyline, washing out with solution of alum or with a diluted acid. In conclusion Dr. Benda gave a theory of hæmatoxyline colouring, which ranged itself close in order with the colouring with logwood customary in technics. In both cases the colouring-matter was applied as lac, the tissue being first saturated with the mordant, and then impregnated with the colouring-matter, which formed in the tissue lacs insoluble in water and alcohol, and only in part capable of being resolved through washing out with the mordants or with acids. Or the colouring-matter might be used in the way of ink, which formed precipitates with the tissues.

GEOLOGY OF TURKESTAN[1]

II.

Turkestan: a Geological and Orographical Description based upon Data collected during the Journeys of 1874 *to* 1880. By J. V. Moushketoff. Pp. 714. With Map and Engravings. Russian. (St. Petersburg, 1886.)

THE view taken by M. Moushketoff and other modern explorers of the region, as to the Aral-Caspian basin having consisted of several large lakes, or rather seas, connected together by outlets, is, in our opinion, the only one which can adequately explain the ulterior changes undergone by the basin during historical time; and it is also fully in accordance with the orographical configuration of the region. These outlets have gradually dried up, and it is probable that the Aibughir and the Balkhan outlets both existed during the historical period.

The basin of the Aral and Sary-kamysh was long maintained by the inflow of water received by the Amu and the Sir. There may have been a period when both joined together before entering the great lake; but later on, the Amu entered the Sary-kamysh, or western part of the double lake; while the Sir flowed into its eastern or Aral part. As the Amu, undermining the Sultan-uiz-dagh hills, gradually moved further east, and finally, finding its way through this range, began to flow into the Aral, the Sary-kamysh lakes, deprived of its water, dried up much more rapidly. The Aral basin, in the meantime, may have increased in size.

As to the Uzboy, which was considered by the earlier explorers as a former bed of the Amu-daria, M. Moushketoff, in accordance with the majority of the more recent explorers, considers it a marine outlet which connected both the great lakes; and the absolute want of any river-deposits and the wide extension of Caspian shells up the Uzboy serve to confirm this view. The drying up of the Aral goes on now very rapidly. The disappearance of the Aibughir gulf; the conversion of the Sary-cheganak gulf into a mere lake; as also that of the Kamyshly-bash, which the Kirghizes remember to have been connected with Lake Aral; together with the numerous facts mentioned by MM. Severtzoff, Borschoff, Meyendorf, Maksheeff, and Schultz, are well known. The observations of MM. Kaulbars and Dorandt furnish most valuable data of the same kind for other lakes of the region: the Sary-kamysh, now 50 feet below the level of the Caspian, covered a surface of no less than 4400 square miles. And we may add that these facts are not isolated ones, but that the same rapid drying up is going on throughout Western Asia: it is the characteristic of the geological epoch in which we now live.

Many most interesting pages are devoted by M. Moushketoff to wind-agencies and to moving sands. His observations on dunes and analogous sand-hills, accompanied by several drawings, will assuredly be most welcome to geologists. M. Moushketoff distinguishes between two different kinds of sand-hills: the dunes, arising on the shores of lakes, and the *barkhans*. Wind is a powerful agency in the formation of both. Recent meteorological observations have shown that north and north-east winds are much more prevalent than any others in the Turan region. On the lower Amu-daria and at Tashkend they are from 50 to 60 per cent. As to the rains they are so scanty that throughout the year their aggregate amount hardly reaches 69 millimetres at Petro-Alexandrovsk, and 73 at Nukus. The evaporation, as appears from M. Stelling's work, is exceedingly great. Thus, while at Kishineff, for instance, the annual evaporation exceeds the annual amount of rain by only one-fifth, it is five times greater than the amount of rain at Astrakhan, three times greater at Tashkend, twenty-seven times at Nukus, and thirty-six times at Petro-Alexandrovsk. The yearly amount of rain being represented by a column 69 millimetres high at Petro-Alexandrovsk, the evaporation is so great that a column of water 2320 millimetres high would be evaporated every year; at Nukus the respective figures are 71 and 1928 millimetres. These climatic conditions would suffice, in M. Moushketoff's opinion, to explain the geographical distribution of the moving sands which appear more especially to the south of Lake Aral.

Now, among these moving sands two different kinds of moving hills should be distinguished; the *dunes* and the *barkhans*. The former are indebted for their origin to the combined action of water and wind; they are disposed in long waves along the shores of the lakes or rivers—these last (the river-dunes) being local and never reaching more than 10 or 15 feet in height. The marine dunes, attaining as much as 50 feet—not more—have lengths reaching to about 700 yards. They arose in consequence of the retiring of the Aral Sea and the prevailing winds. These dunes have the most varied directions, according to the local direction of the former shore-line.

As to the *barkhans* they are indebted for their origin to the agency of the wind alone. They can arise only under certain climatic conditions, and may appear covering any geological formation, like the moving sands o the Ili River, which are due to the destruction of massive crystalline rocks, or the sands of the Sahara, which are a result of the disintegration of basaltic rocks. Their outer shape is quite characteristic, being always that of a crescent, or, to use Middendorff's comparison, it resembles the hoof of a horse. Sometimes two, three, or four *barkhans* are connected together, and then they appear like a succession of crescent-shaped conical hills, connected by their respective horns. Their height is usually from 30 to 40 feet; there are, however, much smaller ones, and a few reach as much as 80 and even 100 feet. The sand of which they consist varies according to the nature of the rocks to whose disintegration they are due; the angles of inclination of their slopes also vary between 30° and 40° on the side turned to the wind, and between 6° and 16° on the opposite side.

On the whole, on seeing these hills, one would refuse, according to M. Moushketoff, to recognise in them a formation due to the sole agency of the wind, but one must witness a storm in the desert to recognise its full force. Still, during a very strong storm, M. Moushketoff did not see the wind moving particles of sand more than 1 to 2 millimetres in diameter.

[1] Continued from p. 119.

We should very much like to go further into an analysis of the interesting observations on the loess, scattered through M. Moushketoff's "Turkestan"; but can only mention that the loess which is widely spread over the region, both on the outskirts of the Tian-Shan and in the neighbouring lowlands, is always accompanied by what the author describes as a "conglomerate," and which is most probably some kind of more or less modified glacial deposit. Both are inseparable, and the loess invariably covers the "conglomerate" when they are met together Of course, the loess extends further in the lowlands, and the "conglomerate" in the hilly tracts. Sometimes there are layers of loess amidst the "conglomerate." As to the loess itself, although mostly quite typical, it sometimes appears stratified to a certain extent; but it does not differ at all from the unstratified loess. M. Moushketoff accepts Richthofen's theory as to the eolic origin of loess; but he does not deny that water spreading over a wide surface at the issue of small depressions of the ground, gives the same typical loess as that which may be considered eolic in its origin.

We ought to notice also a special question discussed at length by M. Moushketoff, namely, his thorough researches, made in company with Prof. Beck, on the nephrite (jade) of which the stone on the grave of Timur at Samarkand is made, as to its chemical composition, micro-structure (represented on a coloured plate), and also the different places where nephrite is found throughout the world. But we must merely commend these interesting researches to the attention of mineralogists.

As may be seen from the foregoing notice, the work of M. Moushketoff is an acquisition of the first importance for all those interested in the geography and geology of Turkestan. The chapters containing the descriptive part of the work will be, for a long time to come, an especially valuable source of varied and reliable information.

P. K.

CHEMISTRY FOR THE GOLD-FIELDS

Chemistry for the Gold-Fields: including Lectures on the Non-Metallic Elements, Metallurgy, and the Testing and Assaying of Metals, Metallic Ores, and other Minerals, by the Test-tube, the Blow-pipe, and the Crucible. By James G. Black, M.A., D.Sc., Professor of Chemistry, Metallurgy, and Assaying in the University of Otago, and Otago School of Mines. 8vo, pp. 569. (Dunedin, 1885.)

THE title "Chemistry for the Gold-Fields" the author justifies by stating in his preface that in writing this book he had three objects in view:—

"First.—To put into the hands of miners and prospectors a guide to enable them to identify, by simple tests and cheap appliances, the valuable ores when they find them.

"Second.—To provide a manual in chemistry, metallurgy, analysis, and assaying for the 'Schools of Mines' which are now being established on the gold-fields of the colony.

"Third.—To provide for his own students in the chemistry, metallurgy, and assaying classes in the University of Otago, a text-book in these subjects introductory to the larger treatises"

The book includes an elementary treatise on the chemistry of the various elements, and on this portion of the book it is scarcely necessary to dwell, as it is claimed that "the feature of the book" is to deal with "such subjects as have a direct reference to the mineral resources" of New Zealand, and "the extraction of the metals from their ores." We propose, therefore, to confine our remarks to that portion of the work which relates more especially to the detection of minerals, the methods for assaying them, and their metallurgical treatment. The ores of each metal are described, their chief physical characteristics being stated, as well as the ordinary blow-pipe tests, and this latter portion of the subject is made more useful by an appendix on the use of the blow-pipe by A. Montgomery, M.A., the brevity of which is greatly to be regretted.

To the metallurgy of zinc the author devotes little more than three pages, nearly half of which is devoted to the abandoned English crucible process. The Belgian process is briefly described, and in half-a-dozen lines the Silesian process is touched upon. With regard to this latter description the author remarks that "various modifications of this process have now, it is said, been adopted in many of the larger smelting works." This remark could with justice have been appended to many of the descriptions of other processes given by the author. In the metallurgy of lead the use of iron for the decomposition of the silicate is not mentioned, and the description of lead-refining is very incomplete, as also is that of the process for the de-silverisation of lead by the aid of zinc; the use of steam for the de-zincification of the lead is not given. In the description of the Welsh process of copper smelting the coarse metal slag is stated to be a ferric silicate—ferric silicates are, as such, rarely, if ever, produced in metallurgical processes. In describing the refining of copper the author gives equations to show that the reduction of the cuprous oxide on poling is due to the products of the dry distillation of the green wood employed; the action of the anthracite spread over the molten metal is not referred to. The electrolytic refining of copper is not mentioned, and electrolytic processes generally, which would be so important in a country like New Zealand, are ignored.

In describing the Ziervogel process the author remarks, p. 344: "When copper pyrites containing silver is roasted, under certain conditions, the iron and copper may be converted into insoluble oxides, while the silver is converted into sulphate of silver which dissolves in water. The presence of mercury promotes this reaction." This at least suggests that mercury should be charged into the roasting furnace. Again, p. 348, Ziervogel's "process is now carried on on a large scale at Freiberg, in Saxony," the fact being that it has long been abandoned there, except as a very minor incident of a portion of the process. The process of pan-amalgamation, as described by the author, is inaccurate. In describing the methods employed for the production of steel, the Siemens "ore and pig" process is not mentioned, and the basic Bessemer process is only referred to by the sentence: "By a recent invention, however, whereby the converter is partly lined with lime, it is said that sulphur and phosphorus are also removed in the Bessemer process."

The author suggests "a rapid process for distinguishing galena from zinc blende, grey antimony ore, and the other mineral sulphides for which it is sometimes mis-

taken," which involves solution, evaporation, &c., for lead sulphate, filtration, and submitting the solution to ordinary chemical tests. This is surely not a method adapted to the use of "miners and prospectors."

With regard to assaying, in the case of copper ores not one of the ordinary methods of assay is given, and the ordinary method for assaying silver ores finds a place in an addendum to the volume. The whole book affords additional evidence of the prevalence of the belief in the fallacy that a chemist must of necessity be acquainted with a subject so dependent on his own, yet so widely differing from it, as metallurgy.

OUR BOOK SHELF

Microbes, Ferments, and Moulds. By E. L. Trouessart. "International Scientific Series." (London: Kegan Paul, Trench, and Co., 1886.)

THIS book, which aims at the instruction in microbes not so much of the medical and scientific as of the general public, is a fairly accurate exposition of the present state of our knowledge of the morphological and physiological characters of moulds and bacteria.

The chapters on fungi and moulds, of the various ferments and yeasts, and their chemistry, are the best parts of the book. Those on bacteria, septic and pathogenic, are less commendable, since they contain a good many dogmatic statements not accepted by bacteriologists. The chapter on laboratory research and culture of microbes is imperfect in its account of the now generally employed methods of cultivation on solid nutritive media.

One of the most conspicuous deficiencies of the book in the eyes of the scientific reader is the one-sided account given by the author of many of the discoveries made in bacteriology, since the works of French authors form as it were the basis of the author's account. It is certainly a novel proposition that "the science of microbes is essentially a French science."

The book is well illustrated, and written in a clear and concise manner.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Luminous Clouds

THE clouds described by D. J. Rowan, on p. 192 in your issue of the 1st inst., seem to have been of the same kind as were described in several letters in NATURE last summer; they were seen by myself in Bavaria. I saw these extraordinary clouds again this year, on the 28th of May, at Freshwater Bay, Isle of Wight, and on the 23rd of June at Bideford. They were seen by A. C. Dixon at Sunderland on the 2nd, 3rd, 13th, 16th, 22nd, and 23rd of June, and on the latter date were very striking. A description of them on the same date, written by E. Greenhow, appeared in the *Newcastle Chronicle*, as seen near Earsdon in Northumberland, erroneously describing them as a kind of aurora. On that night the display at Bideford was comparatively slight: at 10.18 p.m. the upper limit of the clouds distinctly visible was five-eighths of the way from the horizon to γ Andromedæ, and I presume that that was the limit to which the sun was shining upon them; though with field-glasses I could see them very faintly rather higher up.

I never saw them before last summer, and they are quite different from the iridescent clouds that have created such interest the last two winters, resembling them only in their height and brilliancy. If they require a name I hope the word *boreales*, as proposed by Mr. Rowan, will not be adopted; for they appear in the north only because the sun lies in that direction, and if they occurred at any other time of the year, or in any place much further south than this country, their direction would necessarily be different. On all the occasions which I have seen these clouds they have exhibited a very fine structure like cirrus. The colours of the clouds appear to be due to the same cause as the colours of the sky, for they generally correspond with these at similar altitudes, the upper visible portion of the sheet of clouds being green or bluish, and the lower portion a dull yellow, becoming more orange towards the horizon.

Sunderland, July 8 T. W. BACKHOUSE

Re Immisch's Thermometer

IN your article, p. 234, referring to this pretty little instrument, you refer to the appellation "metallic" as not a happy one in describing it. This I pointed out to the maker some time ago, and termed it an *avitreous* thermometer, as glass plays no part in its construction beyond that of a protector to the dial. The certificates of verification are printed with the instrument so designated, and probably the erroneous term will soon drop out of use. I must also crave permission to correct a misprint in your correspondent's statement with regard to the number of avitreous thermometers verified here up to the present date: for 500 read 300. G. M. WHIPPLE,

Superintendent Kew Observatory

Kew Observatory, July 10

Kirby and Spence's "Introduction to Entomology"

WITH reference to a just complaint made by "R. M." in his article contained in NATURE for July 1 (p. 190) about the want of good indexes to books, and specially to the early editions of Kirby and Spence's "Introduction to Entomology," may I venture to inform him that should an index to the latter book be desired by "R. M." or any other reader of NATURE, they have only to apply to "E. E. J.," Camerton Court, Bath, to obtain one *gratis*. I found the book so perfectly useless for want of one, that I made one some years ago, a copy of which was accepted by the British Museum authorities, and is now included in their Catalogue. I have a good many copies on hand, which I am always glad to give away on application.

ON VARIATIONS OF THE CLIMATE IN THE COURSE OF TIME[1]

II.

IF such a periodical variation in the climate does take place, we should be able to trace it in the older formations, as we cannot assume that it first began to operate in the most recent geological age. We must, therefore, try to discover if such variation can be traced in the earlier times.

During the melting of the Norwegian inland ice it left here and there moraines, and on the map drawn by Kjerulf they are seen to stretch in lines more or less continuously across large parts of Southern Norway. On both sides of the Christiania fjord the outside lines, the so-called "Raer," stretch like gigantic ramparts from Moss and Horten south-east and south-west many miles wide through Smaalenene and far into Sweden, and, on the other side of the fjord, through the province of Jarlsberg and Laurvig to Jomfruland outside Kragerö. And behind this outside line of moraines others follow in more or less broken but distinct continuity, one behind the other, through all Southern Norway. These lines show that the

[1] The following is a short abstract from various papers, viz.: "Essay on the Immigration of the Norwegian Flora during Alternating Rainy and Dry Periods" (Christiania, 1876). "Die Theorie der wechselnden kontinentalen und insularen Klimate," in Engler's *Botanische Jahrbücher*, ii. (Leipzig, 1881). "Ueber Wechsellagerung und deren mutmassliche Bedeutung für die Zeitrechnung der Geologie und für die Lehre von der Veränderung der Arten," in *Biologisches Centralblatt*, iii. (Erlangen, 1883). "Ueber die wahrscheinliche Ursache der periodischen Veränderungen in der Stärke der Meeresströmungen" *l.c.* iv. (Erlangen, 1884) Continued from p. 222.

ce did not recede gradually, because it would not then have left behind such great ramparts, but the sand and the gravel would have been spread more evenly. During the melting, however, its edge remained at times stationary, or advanced perhaps a little. At each such event a row of moraines was formed, and as the same are found in large tracts of the country, they cannot be attributed to local circumstances, but we have to assume *that periodical variations of climate were the cause of the manner in which the ice receded.*

We found in the peat-bogs alternately layers of different kinds, peat alternating with remains of forests several times, and we saw how this was easiest explained by periods of change in the climate. But these alternating layers are not peculiar to the peat alone, but found in all stratified formations, loose as well as solid, whether deposited in fresh or salt water, or on land, in all the strata from the Laurentian gneiss to the loose deposits of the present age. Take a geological structure from any age, alternating layers will be found everywhere. Sand alternates with gravel, sandstone with conglomerate, clay with sand, slate with sand or sandstone, marl with clay, chalk with marl, and so on. The layers vary in thickness, from several yards to less than an inch.

The solid rock withers away by the action of air and water in heat and cold; it partly crumbles away mechanically and partly changes chemically. The products of the erosion are carried by wind or running water as dust, in dissolved or original state, and deposited in places more or less remote from those where they were produced. The foaming mountain stream often carries great stones in its course, and the softer the wind and the weaker the current the finer is the matter deposited. When the current becomes weak the gravel sinks first, then the sand, then the clay, and, finally, the chemically-dissolved lime by the animal life in the water. When we, therefore, have a change of beds of different composition through all geological ages, as those mentioned above, it must be due to the circumstance that the speed of the depositing stream was always varying—now increasing, now decreasing.

The *Challenger* Expedition has taught us that all the stratified rocks which geologists hitherto have known must have been formed comparatively near the shore, even if deep-sea formations. They are all of quite a different nature from the strata in the abysses of the great oceans. From this it follows that the variations in the rainfall might have had some influence on the nature of the strata in the known geological formations, since they were formed comparatively near land and are the result of the erosion of the solid rock. A weak river is unable to carry debris far out to sea, but a strong one is capable of supplying the sea-currents with deposits over great areas. When, therefore, the rivers alternately increased and decreased, the sand, clay, and gravel were carried now a greater, now a less distance, into the sea, and thereby the variations of the layers were produced.

It is, however, not the intention to assert that all alternations of layers are due to that long climatic period. When the stratification goes on quickly, and the supply of matter is plentiful, rapid local changes may produce an alternation of strata. In the Norwegian marl-clay, formed during the melting of the inland ice, alternating thin layers of sand and clay are found, varying in colour, sometimes only a quarter of an inch in thickness or even less. These variations must be ascribed to changes during brief spaces of time, and cannot be referred to the long climatic periods. But, of course, such layers are only formed in the immediate vicinity of the coast, and during the constant advance and retrogression of the latter, which may be traced through all geological ages, such shore-formations were most exposed to destruction. They were frequently lifted above the sea, and were more exposed to the destructive agencies—air and currents—than those formed in deeper waters further from the shore. For this reason these quickly-formed layers have at all times been more exposed than others to destruction, and we must, for that reason, conclude that most of the beds which constitute the geological stratified deposits were formed somewhat further from the shore, and that, consequently, the time of their formation was longer. From the thickness of the layer alone it is impossible to form an idea of the time it has taken to form, because in the time a layer in one place upwards of several yards in thickness has been forming, only an inch has formed in another, whilst in a third place in the same time the formation has ceased, or older layers even carried away. But we have a means whereby we may ascertain the time it has taken to form a layer, viz. the study of the remains of the flora and fauna found in the same. The most frequent species have, *ceteris paribus*, the most chance of being preserved. When, therefore, we find that fossils, as is often the case, vary from stratum to stratum, we must assume that this proves that great changes took place in the fauna and the flora during the formation of each stratum. What was stated above with regard to the variations in the peat-bogs of remains of plants from layer to layer *may be applied to variations of strata through all ages.* The examination of the fossils in the strata teach us respect for Time. The fossils vary quickly even in strata of small thickness. In one stratum we find remains of distinct animals and plants, and in the one above—although, perhaps, only an inch above it—we find others quite different. A thin stratum of a couple of inches is sometimes distinguished by peculiar animals and plants, so that the stratum may be recognised over large areas by the aid of the same. When two strata of different nature alternate, it is generally found *that one kind of stratum contains certain fossils, and that those of the others are quite different.* The theory of periodical variations of the climate *explains all this.* Because if the sea-currents varied in strength, the temperature of the water, and consequently the aquatic fauna and flora, must have changed too; with a higher temperature of the sea the moisture of the air and the rainfall must have increased, *and thus a periodical change of the sea-currents would have the effect of causing variations of the strata.* It is exactly such strata of varying nature, and varying forms of fauna and flora, which would build the geological strata of the earth.

We have seen how this theory explains a number of various well-known puzzles to scientific men, viz. the scattered extension of species of plants and animals; the formation of the terraces of shell-banks and shore-lines; the rows in which moraines appear; and, finally, the alternation of peat-layers and various geological strata. It only remains now *to find a natural cause for such a periodical variation of the climate*, but before doing this it is necessary clearly to understand what the theory demands.

It does not require great changes; all the facts on which it is founded may be explained by comparatively small variations in the extremes of temperature and rainfall. No very great variation is required in order that the holly and similar coast-plants should be able to grow by the Christiania fjord, as the theory assumes it once did; because the holly, which cannot stand the winter cold at Christiania (lat. 60° N.), has for many years been successfully cultivated in the open air at Horten, only half a degree further south on the same fjord. And along the coast plants of Oriental origin have, during the last thousands of years, spread from the Christiania and Throndhjem fjords right out to the open shores of Jæderen and Fosen, the former in lat. 58°–59° and the latter in lat. 63°–64° N., and there would hardly be required a very great change to enable them to grow also in the intervening district, the province of Bergen, which would again make their extension continuous.

Whether the surface of a bog becomes covered with forest or not, whether the peat grows or not, whether during the rising the erosion is strong enough to hollow out the shore-line, or the carrying power of the river is great enough for the formation of terraces, whether the edge of the inland ice recedes or advances, whether a deposit of clay or marl is to be found in a certain place near the shore, or whether chalk only is left—*may entirely depend on small variations in the climate, as the conditions will alter as soon as a certain point is reached.* The periodical changes dealt with here were therefore not great; but as they acted simultaneously, and in the same direction, over whole climatic areas, it must be generally-acting forces which caused the same, and not variations in local conditions.

The theory advanced here proves thus that the climate is at all times subjected to periodical changes, the duration of which may be measured in thousands of years, and which act in the same direction within the same climatic area, which for one period are not important, but which, as the alternation of the strata is often remarkably regular, *seem to return after the lapse of a fixed cycle of years.*

It is obvious that periodical changes in the strength of the ocean currents will cause corresponding changes in the climate of the adjacent continents. Thus, for instance, if the warm North Atlantic current, to which North Europe owes its climate, which is mild compared with its latitude, should increase in strength, the climate there would doubtless become still milder. Our shell-banks show that such changes in the temperature of the sea have accompanied climatic variations. We are, therefore, compelled to ask, What is the force which causes this warm sea-current to flow northwards, and may we assume that there is some natural cause effecting periodical changes in the intensity of this force? The question being one as to a climatic period, we must examine the great laws which govern the climate. We must, of course, leave all temporary disturbances of the air out of consideration, and only pay attention to the great and simple laws which are revealed by the synoptic charts of the average distribution of the aërial pressure at various seasons. These charts show us:—in the summer a low pressure over the heated continents, but generally a higher one over the cool oceans; and in the winter a higher pressure over the cold continents, and a lower one over the oceans, which are warmer.

In order to understand this varied distribution of pressure, we shall imagine an atmosphere which everywhere has the same degree of heat and the same height. The warmer the air the more it expands, so that the height of the atmosphere will change if the temperature rises or falls. If we further assume that the air cools or becomes more quickly heated in some places than others, the equilibrium will be disturbed. Over cold areas the height of the atmosphere will decrease. The surface of the atmosphere should thus become uneven, and consequently, in the upper strata of the atmosphere air must flow from the warm regions into the cold ones, so that equilibrium be maintained. For this reason a greater mass of air will lie over cold regions, which have, therefore, a higher atmospheric pressure. But at the surface of the earth, too, the equilibrium will be disturbed, as a higher atmospheric pressure will drive the air from the cold to the warm regions. As long as the temperature of the air varies, movements will be created by the disturbed equilibrium, during which, therefore, air will flow from the cold to the warm regions along the surface of the earth, and *vice versâ* in the upper part of the atmosphere. In winter as well as summer the disturbances of the equilibrium of the atmosphere will proceed from the continents, because the latter are heated and cooled more intensely than the oceans. Over the ice-covered interior of Greenland the sun in the summer cannot create any low pressure, because all its heat is consumed in melting the snow. Even in the summer comparatively cold air and high pressure prevails over Greenland, and this is probably the cause of the atmosphere in the North Atlantic differing from the above-mentioned law, inasmuch as this ocean has a low pressure even in summer. This low pressure, which lies generally near Iceland, is, however, more marked in winter.

The air, according to the law of Buys Ballot, moves *against* the low pressures, so that in the Northern Hemisphere one has the low pressure a little in front to the left when turning the back to the wind. That is but a natural consequence of the rotation of the earth's axis. At lower latitudes this action is more intense. Air, flowing from lower to higher latitudes, retains for a time its original speed of rotation, and will thereby deviate in the direction of the rotation of the earth's axis, *i.e.* towards the east. And *vice versâ* when the air flows from higher to lower latitudes. In this manner southerly winds become south-westerly, and northerly ones north-easterly. In fact, the low atmospheric pressure at Iceland draws the south-west winds up the North Atlantic, and as the cause prevails all the year round, the consequence is that south-west winds blow in this sea summer as well as winter.

The opinion held by Croll, Zöppritz, &c., that winds are the chief cause of sea-currents, is now generally accepted by *savants.* The winds set the surface of the sea in motion, and by frictional resistance the movement is conveyed to lower depths. It depends on the force and the duration of the wind how deep the action will have effect. The main current runs in the direction of the prevailing wind, and its speed is dependent on the average speed of the surface. Winds of short duration are only capable of changing the direction of the current on the surface, but through the *predominance* of such winds through thousands of years, *great currents are created.* Their strength may vary, *but their direction is independent of temporary changes of the wind.* For the upper system of currents, which alone affects the climate, and which reaches to a depth of a couple of hundred fathoms (Mohn), the average direction and force of the wind during the last great epoch are determinal.

Such a great stream is the warm North Atlantic current. It softens the winter even at high latitudes. As the surface imparts heat to the air, the heat lost is replaced from lower depths, and as long as there is a store of heat below the sea will always yield heat to the air.

The mild climate of Norway is, therefore, dependent on this warm current. It runs predominantly in a north-easterly direction, and thus it must, in consequence of the general laws for currents and winds, have run through untold ages, or as long as sea and land have been divided as at present.

We will now see if the force which guides this current is periodically changeable. As we know, the orbit described by the earth round the sun is not circular but elliptical, so that the distance between the two bodies varies according to the seasons; when there is winter in the Northern Hemisphere the earth is nearest to the sun, and the nearer the earth approaches the sun the quicker it travels, so that the winter in the north is shorter than the summer. The difference is five days. In the Southern Hemisphere, on the other hand, the winter is five days longer than the summer. But these relations change through the precession of the equinoxes, the period having a mean duration of 21,000 years. Thus, 10,500 years ago the conditions were the reverse of what they are at present, and the same will be the case 10,500 years hence. The winter at the Northern Hemisphere will then fall when the sun is furthest from the earth, and last longer than the summer, and in the Southern Hemisphere the conditions will be the reverse.

But the orbit of the earth is also subjected to periodical changes, inasmuch as it differs more from the circular

sometimes than at others. The further it deviates from it the greater becomes the difference between the length of winter and summer, and the difference may even amount to more than thirty days every year. The length of winter and summer varies therefore in the course of 10,500 years, and the difference increases the more the earth's orbit deviates from the circular. During the 10,500 years in which the winter is longer than the summer there will be several thousand more winter days than summer ones, and in the second half-cycle there will be as many thousand less. Even at present, when the orbit deviates but little from the circular, the excess of winter or summer days for each half-cycle is more than 50,000, and when the deviation is greatest it amounts to nearly 220,000 days, or some 600 years.

As the cooling of the continents contributes to preserve the low atmospherical pressure over the oceans, and thus directs the prevailing winds and currents at sea, the winds thus directed, as, for instance, the south-west winds of the Atlantic, must be stronger in winter than in summer. *And this is indeed the case.* The weather conditions differ in summer and winter. Of course south-westerly winds blow predominantly in the North Atlantic and West Europe all the year, *but they predominate more in the winter.* According to Prof. Mohn, their force in the North Atlantic is about three times as great in the winter as in the summer, and similar conditions prevail in the Pacific Ocean. In the southern temperate seas north-west winds, which correspond to south-west ones with us, are equally predominant when there is winter in that hemisphere. It will therefore be seen that the forces which promote the warm sea-currents in our latitude *are most active in the winter.* And the same is the case in the Southern Hemisphere, so that it must be said that the winter favours these currents, whether it falls when the sun is nearest, as with us, or when it is most distant, as in the Southern Hemisphere. From Prof. Zöppritz's studies of the currents it appears that the wind exercises an influence upon the strength of them even long after it has ceased to blow. The action of the winds is summed up through centuries, *and the total recorded in the sea-currents.*

As we know that the wind conditions vary at different seasons, and that the effect of the wind does not cease as soon as it is discontinued, but leaves traces in the sea-currents for a long time after ; so that, in fact, the strength of the current is dependent on the average force of the wind during last great ages—it can hardly be a matter of indifference whether these thousands of days fall as a surplus to winter or summer in the 10,500 yearly half-cycle. When they fall in the winter, the south-west winds must be more predominant than others ; and, correspondingly, when they fall to the summer, weaker. It seems, therefore, reasonable that the currents must increase or decrease as the equinoctial line moves round. When the winter falls in aphelion our warm currents will increase, and when the reverse is the case they will decrease. We should, therefore, now in the Northern Atlantic have a weaker current, and in North-Western Europe less rain and a greater difference between winter and summer heat, *and this is exactly what the theory demands.*

In regions with different weather conditions the case will be different. For instance, in the eastern part of North America north-west winds are more predominant in the winter and south-west ones in the summer. Winter, in aphelion, would here increase the north-west wind, and one might conclude that these parts under such conditions would perhaps thereby obtain a more severe climate, so that it seems evident that variations in the climate will not simultaneously move in the same direction everywhere in the Northern (or Southern) Hemisphere.

From calculations we have elsewhere demonstrated that the varying length of the season alone during the precession of the equinoxes will cause an increase or decrease in the force of the current of several per cent. of the total. And these figures are doubtless below the true ones, but space does not here permit of developing them. We may, therefore, with a high amount of probability conclude *that the precession of the equinoxes causes periodical variations of the climate which are great enough to explain all the facts on which the theory for these periodical variations is based.*

But the eccentricity of the earth's orbit changes so rapidly that in two consecutive half-cycles it is not as a rule the same. Therefore variations in the strength of sea-currents, and consequently also those in the climate in one half-cycle will not be quite balanced in the next, and it might even be possible that greater and more lasting variations of the climate might be caused by the same agencies.

The University, Christiania

VEGETABLE PRODUCTS AT THE COLONIAL AND INDIAN EXHIBITION

IN passing through the various courts of the Colonial and Indian Exhibition the prevailing natural resources of each colony are apparent even to the most unobservant, for while the riches of some countries are to be found chiefly in their vegetable products, the wealth of another is in its mineral resources, and of another in its animals.

Regarding the vegetable products, as might be supposed, some of the most interesting objects from a scientific point of view are those which have the least attraction for the general public, such, for instance, as the large and varied collection from the Straits Settlements, or the interesting exhibits from British North Borneo. Amongst the exhibits from the former possessions are various samples of damar, the botanical origin of which is but imperfectly known ; thus, for instance, are specimens of damar sesa, a fossil resin from Larut, Perak, damar meta kuching, or cat's-eye damar, damar renkong, and others. Another fossil resin new to us is called incense or gum Benjamin. Under the name of buah saga are shown some seeds of an *Adenanthera*, probably those of *A. pavonina*, a seed of which is the unit in the Malay jeweller's weight, equal to 4·33 grains troy. The seeds are also eaten by the natives. The tree is found in India, China, and the Philippines. In India the wood, which is of a red colour, hard, and close-grained, is known as red sandal-wood, and is used as a red dye, as well as for cabinet-making and building purposes. On account of their bright red colour the seeds are used as necklaces. Naturally in countries where the bamboo is abundant we should expect to find numerous illustrations of its uses, and various articles of domestic utility, as well as for other applications besides that of ornament, are shown, some of which are very ingenious, such as a trap called grôgoh, used for catching river fish ; it is somewhat of the shape of an eel-pot, and the body of the trap is made of a single piece of bamboo-stem of about 2 inches diameter, and from 14 to 18 inches long. It is split longitudinally for the greater part of its length into fine strips, these are distended to a wide mouth at the top some 6 or 8 inches diameter, tapering to the point from which they spring, where they form the natural stem. By the addition of other fine strips of bamboo fastened round at short intervals a complete funnel-shaped basket or eel-pot is made, the lower or tubular end of which is formed by the hollow bamboo-stem. The ready way in which the natives adapt natural productions is seen in a very simple spinning-top, which is composed of a flattened acorn of the type of *Quercus placentaria*, through the centre of which a piece of wood is driven. In this division also are some very varied sets of betel-chewing appliances as used by the Malays, including the scissor-like implements used for cutting the betel-nuts ; many of these sets are in deftly-worked brass, while others are in more costly metals.

The collection from British North Borneo has many interesting exhibits, notably some remarkably fine specimens of gutta-percha and india-rubber a magnificent plank of the Sumatra or Bornean camphor-tree (*Dryobalanops aromatica*), the crystallised camphor of which is found deposited in cracks and fissures in the wood, occurring sometimes in very large masses; it is largely used by the Chinese, who prefer it to the ordinary camphor of commerce which is produced in their own country. Bornean tobacco is also a prominent object here, and is exhibited both in bundles of cured leaves as well as in cut form. A favourable report has been obtained of this tobacco, and it has been valued above the average of Sumatra tobacco, for which indeed it has been mistaken even by experts.

In the Hong Kong Court the varied uses to which bamboos and rattans are put are largely represented; the difference, however, in the character of the work to which the stems of these two classes of plants are applied is manifest at a glance, for while the rigid stems of the *Bambusas* are used for the rougher or coarser work, those of the pliable species of *Calamus* form the materials from which the finer basket-work, screens, &c., are manipulated. Various examples of the baker's art in the form of biscuits are shown by the Hong Kong and China Bakery Company, Limited, and it is stated, as an illustration of the capabilities of this bakery, that it can turn out 15,000 pounds of ship biscuits or 10,000 pounds of bread per day.

The British Guiana collection almost adjoins that of Hong Kong. Here, as might be expected from the extent of the forests of the colony and the abundance of large hard-wooded trees, timber takes a prominent place, and some magnificent specimens of the best known woods, such as mora (*Dimorphandra Mora*), greenheart (*Nectandra Rodiœi*), wallaba (*Eperua falcata*), and other well-known and useful timbers are exhibited. The heartwood of these timbers is described as "almost everlasting, the beams of old houses being good for over a hundred years in the most unfavourable circumstances of a tropical climate infested with wood-ants and other vermin." Specimens of tibiserie fibre and hammocks made from it are here exhibited. This fibre, which is obtained from the young leaves of the Eta palm (*Mauritia flexuosa*), is of wonderful strength and tenacity, from it the natives make their strongest and most durable cords and hammocks. It is very easily obtained and in any quantity, and if better known in Europe might become a valuable article of commerce. A fine collection of medicinal and tanning barks are here shown, but unfortunately, like the woods from this colony, comparatively few have other than native names. In the catalogue of exhibits it is stated that "the medicinal barks are very varied; a few are well known, but the majority, having never received the attention of chemists or physicians, are as yet untried, but may possibly be found worthy a place in the Materia Medica. Fair quantities are exhibited, and will be distributed to qualified persons who will undertake to report on their qualities. Most of them are common in the colony, and can be easily procured."

It is scarcely correct to say that the medicinal barks of British Guiana have never received the attention of chemists or physicians, for at the close of the International Exhibition of 1862 some twenty different medicinal barks of the colony were experimented upon and their effects tried in various cases by Mr. Charles Hunter, who was some time House Surgeon to St. George's Hospital. The results of his experiments were embodied in a pamphlet, and published at the time by Messrs. Churchill and Sons of New Burlington Street, but we never heard that any of them came into use in this country, and it is to be hoped that better results may be obtained from the present collections.

JOHN R. JACKSON

WHAT IS A GLACIER?[1]

GLACIERS have become so well known from the graphic descriptions of Carpenter, Forbes, Agassiz, Tyndall, and other explorers, that it seems unnecessary at this time to do more than call attention to a few of their more characteristic features by way of an introduction to what I have written concerning those now existing in the United States.

The formation of glaciers in any region depends primarily on the fact that the amount of snow precipitated during a term of years exceeds the amount dissipated by melting and evaporation. In this manner snow-banks of broad extent are formed, the lower portions of which become compacted into ice. The change from snow to ice is known to result from pressure, and as ice is mobile under pressure, either by reason of its inherent plasticity or as a result of regelation, the weight of this mass tends to change its form, and it thus acquires motion, which takes the direction of least resistance.

The essential characteristic of glaciers seems to be that they result from the consolidation of snow in regions of secular accumulation, *i.e.* above the snow-line, and flow to regions of dissipation, *i.e.* below the snow-line. From these primary conditions result a multitude of secondary phenomena.

For convenience of reference we will divide glaciers into *alpine* and *continental;* not that the two classes are always distinct and separable, but for the reason that typical examples of each are well characterised and capable of specific description. Variations occur in each class which may suggest minor subdivisions.

The glaciers with which we are most familiar belong to the class that have their archetype in the mountains of Switzerland, and occur about high peaks, usually in amphitheatres or *cirques* at the heads of high-grade valleys. The snow that accumulates on high mountains, especially in temperate latitudes, is frequently not completely melted during the summer, and thus tends to increase indefinitely. The *névé* of a glacier is such a snow-field. The gorge or valley leading from every alpine amphitheatre furnishes an avenue of escape for the consolidated *névé*-snow, which is forced out through the opening, and flows for a greater or less distance as a stream of ice. Such in brief is the genesis of an alpine glacier. Every glacier of this class is divided into a *névé*, or snow-region, above, and an icy portion below. The line of demarcation is the *snow-line*. As compact ice occurs also beneath the *névé* from which it is formed, this division of a glacier into two portions applies only to the surface. The division line, moreover, shifts with the seasons; at times, perhaps for many years together, the true glacier ice may be concealed by a snowy covering. The *névé* is composed of granular snow, white or grayish-white in colour, and comparatively free from dirt and stones; below the snow-line the glacier is formed of both porous and compact ice, and is usually concealed more or less completely with rock-debris. From a distance these two divisions are frequently distinctly shown by contrast in colour. The stones and dirt that fall on the *névé* sink more or less deeply into the snow and become buried beneath the next addition, and as the *névé* becomes consolidated and acquires glacial motion, this debris is carried along in its mass. But the region below the *névé* being one in which loss exceeds supply, the snow and ice are melted, and the foreign bodies formerly held in the mass become concentrated at the surface, and are then carried along as moraines. Thus in the *névé* region the tendency is to bury foreign objects, and in the glacier proper to concentrate them at the surface.

All the debris carried by glaciers may be designated in general terms as *morainal* material, but when arranged

[1] From Memoir on "Existing Glaciers of the United States," by Israel C. Russell. Reprinted from the Fifth Annual Report of the Director of the U.S. Geological Survey.

in definite ways it receives specific names. When distributed along the margin of an ice-stream it forms *lateral* moraines. Two glaciers uniting, the right lateral moraine of one combines with the left lateral moraine of the other to form a *medial* moraine at the line of contact, the ice-streams flowing on side by side as a single compound-glacier. The debris carried to the extremity of a glacier and deposited about its foot is known as a *terminal* or *frontal* moraine.

In flowing through a valley ice is subjected to stress, which causes it to fracture and form open fissures termed *crevasses*. When a glacier passes over a steep ascent it becomes broken by a great number of fissures, and not infrequently falls to the base of an escarpment in detached blocks, forming an ice cascade, but heals its scars and flows on as a solid mass below. The fissures formed when a glacier passes over an inequality in its bed are commonly transverse to the direction of flow, but may take other courses, depending on the nature of the obstruction, change of slope, &c. Marginal crevasses, resulting from the friction of the ice-stream against its banks and the consequent more rapid flow of the central portion, usually leave the shore at a moderate angle and tend up-stream.

Glacier ice has been found to exhibit a definite structure, known as lamination, or as ribboned or banded structure, produced by the alternation of thin plates or strata of compact bluish ice with others more porous. As shown by Tyndall's experiments, this arrangement is the result of pressure, and is analogous to slaty cleavage.

Owing to unequal melting, the surface of a glacier is usually extremely irregular, the parts protected by moraines standing in higher relief than the clearer portions. Still further diversity is formed by boulders perched on columns of ice, which they have protected from melting as the general surface wasted away. These are termed *glacial tables*. At other times the ice bristles with a multitude of acicular pyramids, or is melted into holes and ice-wells, each having a stone or mass of dirt at the bottom.

The melting of the surface of a glacier gives rise to many rivulets and brooks, which course over it in channels of ice, frequently plunging into yawning crevasses, and finally joining the sub-glacial stream that issues from beneath every glacier. These glacier-born streams are always heavy with comminuted rock, ground fine by the moving ice.

Such in brief are the principal characteristics of alpine glaciers.

At the present time continental glaciers are confined to the arctic and antarctic regions, and have been less thoroughly explored than the alpine forms common in more temperate latitudes. Glaciers of this class are characterised by their broad extent and by not being confined by definite walls; their *névés* are large, frequently covering nearly the entire glacier, and their surfaces are free from boulders and debris, for the reason that they are regions of accumulation, and also because mountains seldom rise above them. Owing to inequalities in the country over which these great fields pass, they are not infrequently broken by crevasses; and, as on smaller glaciers, the melting of the surface gives origin to numerous streams, frequently of large size, which become ponded and form lakes in basins of ice, or plunge into open fissures and disappear in the body of the glacier. Existing continental glaciers are believed in all cases to flow from the interior towards the coast, and hence may be considered as acquiring motion in all directions from a centre of accumulation. When alpine glaciers increase sufficiently to cover an entire mountain-range and form a confluent ice-sheet, they approach and may pass into the continental type. It is not impossible that a mountains range of very modest dimensions might give origin to a quaquaversal glacier of vast proportions. It is perhaps not out of place to suggest in this connection that the glaciers which formerly covered the New England State and Canada were of this character.

In framing a definition of a glacier it is evident that we must include both alpine and continental types, and also embrace the secondary phenomena that are commonly present. A glacier is an ice-body originating from the consolidation of snow in regions where the secular accumulation exceeds the dissipation by melting and evaporation, *i.e.* above the snow-line, and flowing to regions where loss exceeds supply, *i.e.* below the snow-line. Accompanying these primary conditions many secondary phenomena, dependent upon environment, as crevasses, moraines, lamination, dirt-bands, glacier-tables, ice-pyramids, &c., may or may not be present. Thus, glaciers even of large size may exist without moraines; in such an instance glacier-tables, ice-pyramids, ice-wells, &c., would be absent. We may conceive of a glacier flowing through a channel so even that it would not be broken by crevasses, but such instances must be extremely rare. The most common of the numerous secondary features seems to be the laminated structure of glacial ice, but even this is not always distinguishable in ice-bodies that are unquestionably true glaciers.

Although the definition we have presented may assist in understanding the nature of a glacier, yet it is manifestly open to objections. If we consider the snow-line as defining the limit between the *névé* and the glacier proper, it is evident that there must be numerous exceptions to the rule. As before remarked, during certain years, and in many instances for a term of years, the snow-line is much lower than at other times, and may completely conceal the glacier beneath. Again, an ice-stream may terminate in the sea and be broken up and form icebergs before the differentiation into *névé* and glacier proper has been reached.

From all that has been determined concerning the nature of glaciers it is evident that they form one of the transition stages in the history of the snow that falls in certain regions, and like genera and species in the organic kingdom cannot be limited by hard-and-fast lines, but may be classified by comparison with typical examples. From the snow, hail, and frozen mists of a mountain-top are formed the accumulations of granular ice-snow which we call a *névé*. By pressure and alternate melting and freezing, the *névé* passes into compact ice, which acquires motion and is termed a glacier; but the plane of separation is indefinite, and one merges into the other by insensible gradations.

The morainal material carried by glaciers is deposited when melting takes place, and frequently forms characteristic accumulations that still retain the name of moraines. The debris along the border of an ice-stream is frequently left as ridges or irregular terraces on the sides of a valley, marking the former height of the ice-flood. At various stages in the retreat of the ice the lateral moraines are united by terminal moraines which cross the former bed of the glacier in irregular but usually crescent-shaped piles, between which the valley bottom is usually deeply filled with unassorted debris, and frequently occupied by lakelets. When a glacier is prolonged from the mouth of a valley on a plain, it builds out its lateral moraines perhaps for many miles, and when it retreats these are left as parallel embankments, not infrequently hundreds of feet high and sometimes miles in extent.

The movement of glaciers causes friction, which results, as the study of living glaciers has shown, in the smoothing and scratching of the rocks over which the ice passes. The boulders, pebbles, and sand held in the bottom and sides of the glacier produce smooth and polished surfaces, crossed by scratches and grooves having an exceedingly characteristic appearance, which, when once understood, it is difficult to mistake for the results produced by other

agencies. While the rocks beneath a glacier are being worn and rounded, the stones set in the ice are in turn battered and scratched and often ground down to plane surfaces that are not infrequently polished and covered with glacial striæ.

As a rule, alpine glaciers follow pre-existing drainage valleys, which they enlarge and broaden. As frequently stated, a stream-cut gorge is distinctly V-shaped, but after being occupied by a glacier it is found to have become U-shaped in cross-section.

The records of glacial action looked for by geologists are: deposits of morainal material, which frequently differs from the adjacent country rock, and may occur in an irregular manner or be grouped definitely as lateral and terminal moraines; boulders perched in fortuitous positions, as on steep slopes and hill-tops; smoothly rounded rocky knolls; polished and scratched rock surfaces; rock-basins, &c.

NOTES

It is stated that the forthcoming "Life and Letters of Charles Darwin," by Mr. Francis Darwin, will contain a brief autobiographical fragment.

Mr. Murray announces a new edition of Darwin's work on "The Expression of the Emotions in Man and Animals," with the author's latest corrections.

We learn from the *Times* that Dr. Hermann Abich, the distinguished Austrian naturalist, died at Vienna on the 1st inst. at the advanced age of eighty years. He was born at Berlin on December 11, 1806, and attained the grade of Doctor in the University of that city before he was twenty-five. His first scientific tours were in Sicily and Italy. He then became Professor of Mineralogy at Dorpat, and devoted most of his leisure during his residence in Russia to travels in the Caucasus, Armenia, and Northern Persia. His earliest published work was on Vesuvius and Etna in 1833–34, and his latest seems to have been brought out in 1862 on the Geology of Daghestan. By his own request his remains were removed to Gotha for the purpose of cremation.

With reference to the recent catastrophe by which the King of Bavaria and his physician lost their lives, *Science* notes that Dr. Gudden is a sad loss to science, for he was one of the most noted authorities in the sphere of nervous and mental diseases. He has also been at the head of a laboratory in which investigations of the fine anatomy of the brain, spinal cord, and sense-organs have been carried on. He has given his name to a manner of studying the connections of the nervous system which is as ingenious as it has proved fruitful of results. His method consists in extirpating a sense-organ or other part of an animal when young, and then allowing the animal to grow up. At death the animal is examined, and the fibres which have failed to develop will thus be marked out as the paths of connection between the extirpated sense-organ and the brain-centre. For many years he had been at work on the problem as to the mode of connection between the retina and the brain, but his results are not yet before the public.

According to *Science* the first circular of the local committee at Buffalo of the American Association for the Advancement of Science, announces that the meetings will be held in the recently enlarged high-school building. Reduced rates have been obtained over many of the railroads, most of which allow a return ticket at one-third of the usual fare. The Western Union Telegraph Company will place its lines and district telegraph system at the service of members. The Botanical Club of Buffalo is arranging an excursion and reception for the Botanical Section, and the local Entomological Club is doing the same kind service for the Entomological Section. The address of the local secretary is Dr. Julius Pohlman, Buffalo, N.Y.

As our readers are aware, it has been resolved to mark the memorable event of the attainment, on August 31 next, of his hundreth year by the venerable father of modern science, "Le Doyen des Étudiants," as he loves to call himself—M. Chevreul—by striking a medal in his honour. The execution of this medal has been intrusted to M. Roty, old "pensioner" of the Academy of France, at Rome. Contributions towards the commemorative medal are, of course, not to be limited to France, but will embrace the whole scientific world, which everywhere alike claims the author who extended the bounds of science as its honoured citizen. Subscriptions, which will be received up to the 22nd of this month, may be addressed to the President of the Committee, 8, Rue Guy-de-la-Brosse, Paris. A list of the subscribers will accompany the medal, which is to be presented to M. Chevreul on his centenary day, and if the amount of the subscriptions allows of it, a copy of the medal will be sent to the subscribers.

At the sitting, on June 7 last, of the Academy of Sciences at Paris, M. Halphen delivered an address in praise of the labours of M. Bouquet, his immediate predecessor in the seat he holds in that body. From the foundation of the Academy down to the present time, the duty of eulogising departed members has devolved exclusively on the Perpetual Secretaries at the anniversary meetings. The annual death-rate of members has, however, of late been such that a large number of them were in danger of disappearing from the roll without any formal record of their services. The initiative thus taken by M. Halphen was followed up at the next meeting. This step has, of course, been taken in imitation of the arrangements of the Académie Française, in accordance with which each incoming member is required to eulogise his predecessor at a special meeting, an answer being also given in the name of the Academy by another member appointed for that purpose.

Recent soundings have given the following depths for the different Swiss lakes:—Constance, between Uttwyl and Friedrichshafen, 255 metres; Geneva, between Rivaz and Saint-Giugolphe, 256 metres; and between Lausanne and Evian, 330 metres; Brienne, 261; Thun, 217; Lucerne, between Gérau and Rueteren, 214 metres; Zug, 198; Neuchatel, 153; Wallenstadt, 151; and Zürich, 143 metres.

According to Prof. Heim, of Zürich, the total number of glaciers in the Alps is 1155, of which 249 have a length of more than 7500 metres. Of this number the French Alps contain 144, those of Italy 78, of Switzerland 471, and of Austria 462. The total superficial area of these glaciers is between three and four thousand square kilometres, those of Switzerland amounting to 1839 kilometres. The greatest length is reached by the Aletsch glacier, which is 24 kilometres long. As to thickness, it will be remembered that Agassiz, when measuring a crevasse in the Aar glacier, did not reach the bottom at 260 metres, and that he calculated the depth of the bed of ice at a certain point of this glacier at 460 metres.

We have received the *Bulletin* for the past year of the Society for Indo-Chinese Studies of Saigon. Amongst the papers is one by that indefatigable student, Dr. Tirant, on the odoriferous woods of Cochin China, which, though numerous in variety, are of four principal kinds, the most important being aloes and sandalwood. We have already noticed a series of papers by the same writer on the fishes and reptiles of Cochin China. Another interesting paper deals with the textile plant *Sansevıera* as found in Cochin China.

A Commission composed of MM. Becquerie, Berger, and Mascart, having been appointed to examine the question of the

safety or danger of erecting a tower to the height of 300 metres, as proposed, in the Champ de Mars, on the occasion of the forthcoming Universal Exhibition, has reported that there is no danger in connection with such a structure if special precautions are taken for its non-insulation. The tower acting as a lightning conductor would, on the contrary, they explain, serve to protect the whole of the Champ de Mars from injury by lightning if the rules laid down by the Commission on lightning conductors were applicable in the case of so exceptional an altitude.

THE report for the current year of the Coventry Free Public Library is a very encouraging document. It shows increase in all directions—in the number of borrowers, the number of books issued, and a large increase in the number of volumes owned by the Library. All the excellent work done by the Institution is paid for by a trifling rate producing a little over 500*l.*, supplemented by the assistance of a private book club. The tables appended by the Chairman, Mr. Odell, showing the number of books issued in each class of literature, the monthly totals and averages, the ages of the borrowers, and more especially the occupations of the latter, are very suggestive. In these days, when more than ever we have, politically speaking, to "educate our masters," the record of the work of the Coventry Free Public Library is very gratifying.

WE have received from Tokio a copy of a Japanese scientific journal (apparently the NATURE of Japan), which has already reached its third volume and fifty-sixth number. It is printed throughout in Japanese, being much the same shape as NATURE, and containing forty-eight pages in each number. The issue before us contains a lecture on human parasites, by Prof. Ijima; some remarks on the historical methods of the Chinese school, by Mr. Suyematsu, formerly of Cambridge; the third of a series of lectures on physical geography by Prof. Kotō; a paper on "Some Phenomena I have witnessed," and another on methods of treating pebrine, by a teacher in the Kornaba Agricultural College. The notes are also of a very general character: they refer to "some simple physical experiments"; an alloy that expands with cold; the uses of coffee; refining ores by electricity; the strength of paper; a new sweet compound; animal bone industry; hypnotism; the Universal Meridian and Time Conference, &c. Then follow letters to the editor, and finally a report of a meeting of the Tokio Physico-Mathematical Society. No proof is wanted nowadays of the remarkable scientific progress in Japan; if it were, it would be supplied by the fact that a journal of this high character can live and apparently flourish.

WE have also to acknowledge the receipt from the Imperial Meteorological Observatory of Japan of the "Monthly and Yearly Means, Extremes, and Sums for the Years 1883, 1884, 1885," with an appendix on observations of clouds. There were twenty-seven stations, including four in Yezo and one in Corea.

AN interesting work which has just been published in the *Bulletin* of the United States National Museum (No. xxx. pp. 113-81) is an annotated catalogue of the published writings of Dr. Charles Abrathar White, the distinguished palæontologist to the United States Geological Survey, and the occupant of several other important scientific positions. The editor is Mr. J. B. Marcou, whose object has been to note everything containing any expression of Dr. White's views on scientific subjects, as well as his more elaborate works. The annotations which accompany the catalogue were drawn up mainly from data furnished by the author himself, and all expressions of opinion on geological and palæontological subjects are his own. The catalogue contains in all 151 entries, ranging from articles in scientific periodicals to his contributions on invertebrate palæontogy in the annual reports of the Geological Survey. The whole represents an almost incredible mass of scientific work, performed as it was in a brief quarter of a century, 1860-85.

WE are glad to notice that Dr. White's important work on the Cretaceous invertebrates of Brazil, which were collected by the Imperial Geological Commission under the direction of the late Prof. Hartt, is now in process of publication at Rio de Janeiro by the Brazilian National Museum. It is to appear in the Portuguese and English languages, and will be illustrated by twenty-eight lithographic plates; 214 species in all are published and figured in this work, of which 116 species are diagnosed as new. Four new genera are proposed—three of Gasteropoda, and one of Echinoids. The former are *Orvillia*, *Cylindritella*, and *Cypræactæon*. The latter is *Heteropoda*, the generic diagnosis of which was supplied to the author by Prof. P. de Loriol, of Geneva.

THE following facts exemplify the strong migratory instincts of trout. At the fish culture establishment at Delaford, where the utmost care is taken to isolate the various species of Salmonidæ, a few of the fish occasionally are found in ponds long distances from those in which they were originally located. Considering that each pond is so constructed as to prevent such a contingency, the occurrence is very remarkable, and can only be accounted for in two ways, viz. that the fish either burrow through holes that probably are made by rats and moles, or they jump out of the water and so proceed to the next pond. It is not likely that they are borne thence by birds, as the appearance of the fish on the occasions referred to does not justify such an assumption. It will be interesting to inquire further into the subject with a view of eliciting the real facts of the case.

A FISH Culture Conference is to be held at the Colonial and Indian Exhibition on July 26 at the instigation of the National Fish Culture Association. The Marquis of Exeter will preside, and papers will be read by Mr. J. Willis-Bund, the Rev. C. J. Steward, Mr. Oldham Chambers, and others, upon fresh-water and marine fish. The Conference will commence at 10.30 a.m. and last until 10 p.m.

A PAIR of electric eels (*Gymnotus electricus*) arrived the other day at the Colonial and Indian Exhibition Aquarium from British Guiana, but have since unfortunately died. They were very fine specimens, and measured 4½ feet in length, their normal size being 6 feet. They require a temperature of 75°, and provided the water is maintained at this standard they will live and thrive in captivity. The water should not be too deep, however, and must be kept clean.

FROM the report issued by the Central Meteorological Institute of Sweden for last year it appears that there are thirty-four public stations for observation, and some half-a-dozen private ones, in that country. In addition to these there are nearly 400 places where the fall of rain is registered, and other partial observations made. These observations have been duly published in the Institute's journal, "Monthly *Résumé*" of the weather in Sweden, edited by Dr. H. E. Hamberg, which has now reached its sixth year of publication. In addition to this, the publication of a short climatological description of each country, founded on the observations of the last twenty-six years, has been continued, whilst Dr. Hamberg has added an important contribution in the shape of the work "On the Influence o Forests on the Climate of Sweden." The twenty-second part of a work "Meteorological Observations in Sweden," a *résumé* of the observations made at the public meteorological station, has also appeared, and finally synoptical tables have been

framed of the weather at all stations on any day of 1884, showing the quantity and nature of the rainfall, thunder, fog, dew, frost, transparency of the air, "sun-snake" (a phenomenon chiefly observed in the northern part of Sweden), aurora borealis, &c. Reports on the forming and breaking up of the ice have been received from fifty-eight stations, besides seventy-seven observations of periodical features of animal and vegetable nature.

THE Swedish Academy of Sciences has issued a work entitled "The Correspondence of Carl von Linnæus," containing a record of all the correspondents of this famous naturalist, Swedish as well as foreign, with their addresses, date of birth and death, &c., as well as the date of each letter to and from.

THE first African city lighted by electricity was not Algiers or Cairo, but Kimberley, with forty-two Brush lamps, each of 2000 candle-power. The current is also utilised there for the killing of dogs, a step suggesting the execution of death sentences by the same means, as proposed in America and in France by M. Charson, a member of the Senate.

MR. R. N. CUST, the Secretary to the Royal Asiatic Society, is engaged on a work on the languages of the tribes of Polynesia, including those of Australia.

THE additions to the Zoological Society's Gardens during the past week include a Squirrel Monkey (*Chrysothrix sciurea* ♂) from Guiana, presented by Madam G. Sangiorgi; a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. D. Evans; a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Capt. Pitman; a Common Cormorant (*Phalacrocorax carbo*), British, presented by Mr. O. Moulton Barrett; two Golden Eagles (*Aquila chrysaetus*) from Scotland, a Lined Finch (*Spermophila lineola*) from South America, deposited; two Ostriches (*Struthio camelus* ♂ ♀) from North Africa; a Lear's Macaw (*Ara leari*) from South America; a Lineolated Parrakeet (*Bolborhynchus lineolatus*) from Mexico, purchased; a Bennett's Wallaby (*Halmaturus bennetti* ♀), a Vulpine Phalanger (*Phalangista vulpina* ♂), three Canadian Beavers (*Castor canadensis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE STRASBURG OBSERVATORY.—Herr W. Schur has published, in No. 2736 of the *Astronomische Nachrichten*, a supplementary report on the work done at the Strasburg Observatory during the ten months preceding May of this year, so as to exhibit the state of the instruments and of the computations relating to the observations made with them on the eve of his departure for Göttingen, where he has been appointed Director in the room of the late Prof. Klinkerfues. During the interval to which the report refers, Herr Schur was chiefly occupied with observations of the moon with the altazimuth and of comets with the great refractor, also with the examination of the micrometer-screw of the latter instrument. The meridian-circle has chiefly been employed in the observation of southern stars—amongst others the eighty-three stars of Auwers' Southern Fundamental Catalogue, and certain stars for investigating astronomical refractions. The direct and reflection observations to the end of the preceding year give for the geographical latitude of the meridian-circle, $+48° 35' 0''.11$, which agrees well with a former determination with Repsold's transit, using Horrobow's method, viz. $+48° 35' 0''.23$. In former reports Herr Schur has drawn attention to the discordance between the nadir points determined with observer north and observer south, which, for his observations, amounts to a considerable quantity; in the mean, from a large number of observations, ½ (north–south) being as much as $+0''.50$. This large value agrees both in sign and in magnitude with the quantity determined from observations of zenith stars for similar positions of the observer, viz. $0''.77$, and Herr Schur concludes that his observed zenith distances of stars require a correction of about $-0''.6$. In the case of the other Strasburg observers, the corresponding correction is comparatively insignificant. Herr Schur's successor at Strasburg is Dr. Kobold.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 JULY 18–24

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 18

Sun rises, 4h. 6m.; souths, 12h. 5m. 56·5s.; sets, 20h. 6m.; decl. on meridian, 21° 1' N.: Sidereal Time at Sunset, 15h. 52m.

Moon (two days after Full) rises, 20h. 42m.*; souths, 1h. 31m.; sets, 6h. 27m.; decl. on meridian, 14° 5' S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° '
Mercury	6 41	13 54	21 7	13 21 N.
Venus	1 33	9 38	17 43	21 46 N.
Mars	11 3	16 48	23 33	3 38 S.
Jupiter	10 9	16 18	22 27	0 58 N.
Saturn	3 7	11 15	19 23	22 20 N.

* Indicates that the rising is that of the preceding evening.

Occultations of Stars by the Moon (visible at Greenwich)

M signifies maximum; *m* minimum.

Meteor Showers

Meteors begin to be somewhat numerous in the latter half of the present month. Amongst the radiants represented are the following:—Near π Andromedæ, R.A. 10°, Decl. 38° N.; near β Cassiopeiæ, R.A. 6°, Decl. 58° N.; near η Draconis, R.A. 245°, Decl. 64° N.; near σ Serpentis, R.A. 266°, Decl. 12° S.; near α Cygni, R.A. 312°, Decl. 46° N.; from Lacerta, R.A. 342°, Decl. 40° N.; and the great *Perseid* shower, maximum August 10, radiant R.A. 45°, Decl. 56° N., begins to furnish individual meteors about this time.

GEOGRAPHICAL NOTES

ACCORDING to the *Colonies and India*, the Secretary of the Victorian branch of the Geographical Society of Australasia has written to the Royal Society of Victoria asking the latter to appoint a committee to confer with that already appointed by the former Society on the question of sending an exploring expedition to the Antarctic regions. It is urged that a conference should take place as soon as possible, and that various scientific associations should be invited to co-operate in sending out one or more expeditions.

THE latest news from the Chitral Mission is that Col. Lockhart is returning to India from Zebah, in Badakshan, leaving Col. Woodthorpe in charge of the party.

IT is stated that Mr. A. R. Colquhoun, who is at present Civil Commissioner at Mogoung, in Upper Burmah, is about to start

on a journey of exploration into Upper Assam, and the regions lying between this and Burmah.

THE latest official information concerning Dr. Wilhelm Junker, the African traveller, comes from Zanzibar. It reports that while he was staying with the King of Unyoro, the latter was attacked and defeated by the King of Uganda. The King of Unyoro and Dr. Junker succeeded, however, in making their escape. Dr. Junker lost all his collections, but saved his journals.

AT the March meeting of the Geographical Society of Stockholm it was decided not to distribute the *Vega* medal—the greatest honour the Society can confer—this year. Only three travellers have as yet received it, viz. Nordenskjold, Pallander, and Stanley. The *Vega* fund was awarded to Dr. F. Svenonius, for explorations in the Lapland highlands during the summer.

A RECENT number of the *Verhandlungen* of the Berlin Geographical Society (Band xiii. No. 5), contains an important paper on Corea, by Dr. Gottsche, who travelled widely over the peninsula on behalf of the Japanese Government. During two journeys he traversed all the eight provinces of the country, and visited 80 of the 350 district towns. The general features are already tolerably well known to English students from Mr. Carles's reports laid before Parliament, and his paper in the *Proceedings* of the Royal Geographical Society, but as Dr. Gottsche is a geologist, and travelled specially for scientific observation, he supplements Mr. Carles's papers in this direction. The climate, he shows by meteorological tables, lies between that of Japan and of North China, while in the North the climate in winter is of almost Siberian rigour. As for the geological formation, granite, gneiss, and crystalline schists play a predominant part. Here and there these are broken by the older volcanic formations, as diabase and quartz porphyry; palæozoic strata occur rarely, and the later sedimentary formations not at all. Active volcanoes do not exist on the mainland, and earthquakes have been unknown within the memory of man. The only metal in which Corea is rich is iron; the belief that gold abounds is a delusion. The fauna is rich, and of much interest, for palæarctic and sub-tropical types meet here. With regard to the flora, unfortunately a large portion of Dr. Gottsches' collection was lost, and the remainder was handed to Dr. Engler of Breslau for examination and report. In conclusion, he says that though Corea may never be popular with the ordinary traveller for pleasure, it will well repay the visitor on scientific objects intent. Prof. Enting, who travelled in the interior of Arabia in 1883-84 on an antiquarian mission, especially in search of inscriptions, gives a long and comprehensive account of the regions through which he went.

THE new number (Heft ii. Bd. 9) of the *Deutsche Geographische Blätter*, the organ of the Geographical Society of Bremen, contains the conclusion of Dr. Oppel's paper on the Congo basin. The present instalment refers to the explorations of past years, the lower, central, and upper Congo region, north and south of the stream, the climate, meteorology, botany, zoology, ethnography, &c. It will thus appear that the paper is an encyclopædic one on the great West African river. The next paper is a continuation of Herr Valdau's account of his journey to the north of the Cameroons, especially around Lake Mbu, and between that and Balundu, and the coast. Herr Steinvorth gives a most interesting account of a little Slav colony or oasis in Hanover called the Hanoverian Wendtland, where the people down to this day have in great part preserved their original speech, customs, and other peculiarities. The writer describes all these in some detail, and comes to the natural conclusion that here we have not a pure Wendt people, but one largely mixed with Germans, and thinks, after discussing the peculiarities of the dialect spoken, that this colony is worthy of the attention of the student of comparative language. This is followed by a general article (which is anonymous) on the new Chilian province of Tarapaca, dealing especially with the silver mines and saltpetre industry. Herr Seelstrang supplies a paper of more direct geographical interest on the region about the source of the Rio Chubut, hitherto one of the least-known parts of the Argentine Republic. The rest of the number (which is of considerable size) is occupied by geographical intelligence, reviews of books, &c.

IN the *Bolletino* of the Italian Geographical Society for May, Signor Sommier describes the excursion which he made with Signor G. Cini to Cape North in January 1885. Some interest attaches to this journey, which is the first made across Lapland and Finland in midwinter for purely scientific purposes. The travellers proceeded by train from Christiania to Throndhjem, and thence by steamer in darkness and storm to Hammerfest and Skarsvaag, in the island of Magerö, the northernmost group of habitations in Europe, and the nearest permanent settlement to Cape North. Here they received a friendly welcome from the local "Landelsmand," and reached the goal of the expedition on foot with much greater ease than had been anticipated. The weather was unusually calm and mild, with a temperature of only $-2°$ C. At some points the evergreen lichens and other growths (*Betula nana*, *Empetrum nigrum*, *Diapensia lapponica*, &c.) were visible through some centimetres of transparent ice clothing the surrounding rocks. The only animals seen, besides the eider and other water-fowl, were the raven, crow, magpie, Arctic fox, and frankoline, the latter (*Lagopus mutus*) everywhere present in large numbers. Several photographs were taken, and after a stay of eleven days in the neighbourhood, during which the glass never fell below $-16°$ C., the travellers returned by water to Hammerfest and Bossekop, at the head of the Alten fjord. Thence the route was continued overland under great hardships—eastwards to Lake Enare, southwards through Kittilä to Haparanda, and round the west side of the Gulf of Bothnia to Sundsvall, whence Stockholm was reached by train. At Karasjok, on the road between Bossekop and Enare, the travellers made the acquaintance of the same Lapp family that visited London last year, and much valuable information was collected on the Lapps, Quans, and northern Finns. This forms the subject of two communications sent by Stephen Sommier to the *Archivio per l'Antropologia e l'Etnologia* (xvi., 1, 1886), and separately printed under the title of "The Lapps and Northern Finns." The account of the trip to Cape North has also been issued in separate form by the Italian Geographical Society (Rome, 1886).

THE LUNAR SURFACE AND ITS TEMPERATURE

A MONOGRAPH by the writer, relating to the temperature of the lunar surface, read before the American Academy of Science, September 1869, contained the following:—"Are we not forced to dissent from Sir John Herschel's opinion that the heat of the moon's surface, when presented to the sun, much exceeds that of boiling water? Raised to such a high temperature, our satellite, with its feeble attraction, could not possibly be without an envelope of gases of some kind. Indeed, nothing but the assumption of extreme cold offers a satisfactory explanation of the absence of any gaseous envelope round a planetary body, which, on account of its near proximity, cannot vary very much from the earth as regards its composition. The supposition that this neighbouring body is devoid of water, dried up and sunburnt, will assuredly prove one of the greatest mistakes ever committed by physicists." This assertion was based on demonstrations showing that the circular walls of the great "ring mountains" on the lunar surface are not, as supposed, composed of "mineral substances originally in a state of fusion." The height and diameter of these walls being recorded in "Der Mond," computations based on the safe assumption that the areas of their transverse sections cannot be less than the square of their height, establishes the important fact that the contents of the wall of, for instance, Tycho, the circumference of which is 160 miles, height 2·94 miles, amounts to $2{\cdot}94 \times 160 = 1382$ cubic miles. The supposed transfer of this enormous mass, in a molten state, a distance of 25 miles from the central vent imagined by Nasmyth, and its exact circular distribution at the stated distance, besides its elevation to a vertical height of nearly 3 miles, involve, I need not point out, numerous physical impossibilities. Other materials and agencies than those supposed to have produced the "ring mountains" must consequently be sought in explanation of their formation. A rigid application of physical and mechanical principles to the solution of the problem proves conclusively that water subjected successively to the action of heat and cold has produced the circular walls of Tycho. The supposition that these stupendous mounds consist of volcanic materials must accordingly be rejected, and the assumption admitted that they are inert glaciers which have become as permanent as granite mountains by the action of perpetual intense cold.

Independently of the foregoing demonstration, the fallacy of the volcanic hypothesis will be comprehended by its advocates on learning that the quantity of lava requisite to form the circular walls of Tycho would cover the entire surface of England and Wales to a depth of 125 feet.[1]

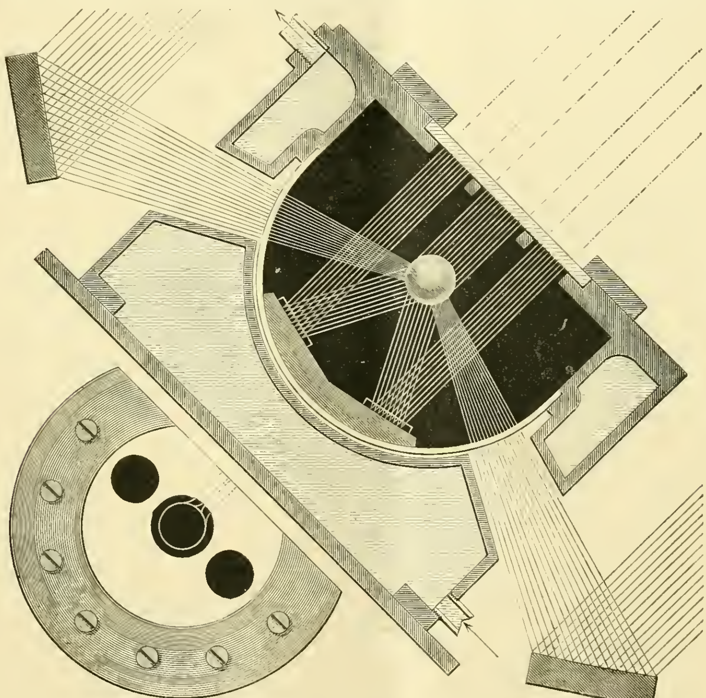
Before proceeding further with our demonstration it will be necessary to establish the maximum temperature which solar radiation is capable of imparting to the lunar surface. This temperature, of course, varies with the distance of the primary and its satellite from the sun. By means of an actinometer the bulb of whose thermometer receives an equal amount of radiant heat on opposite sides, I was enabled to determine with desirable accuracy, sixteen years ago, that, when the earth is in aphelion, solar radiation on the ecliptic imparts a maximum temperature of 67°·2 F., and that the retardation of the radiant energy occasioned by the want of perfect atmospheric diathermancy reaches 0·207. Consequently the temperature produced by solar radiation at the boundary of the terrestrial atmosphere is

$$67 \cdot 2 \times 1 \cdot 207 = 81^\circ \cdot 11 \text{ F.},$$

when the earth is in aphelion. Agreeably to observations during the winter solstice, compared with observations at midsummer, at equal zenith distance, the augmentation of solar intensity when the earth is in perihelion amounts to 5°·84 F.; hence the temperature produced by solar radiation reaches

$$81 \cdot 11 + 5 \cdot 84 = 86^\circ \cdot 95 \text{ F.},$$

when the rays enter our atmosphere during the winter solstice. It should be observed that on theoretical grounds the increase of temperature, when the earth is in perihelion, will be in the



Captain Ericsson's Pyrheliometer.

inverse ratio of the *dispersion of the solar rays*; hence, as the aphelion distance is to the perihelion distance as 218·1 to 210·9, it will be seen that the temperature produced by solar radiation when the earth is in perihelion will be

$$\frac{218 \cdot 1^2 \times 67^\circ \cdot 2}{210 \cdot 9^2} = 71^\circ \cdot 86 \text{ F.}$$

Adding 0·207 for retardation caused by imperfect atmospheric diathermancy, solar intensity during the winter solstice will be

$$71 \cdot 86 \times 1 \cdot 207 = 86^\circ \cdot 73 \text{ F.}$$

Calculation based on *observation*, as before stated, proves that the perihelion temperature is 86°·95, thus showing a trifling discrepancy between theory and observation.

[1] Area of England and Wales, 58,320 square miles; contents of the walls of Tycho, 1382 cubic miles; hence $\frac{1382}{58320} \times 5280 = 125 \cdot 12$ feet.

Adopting 86°·73 as correct, it will be found that the yearly *mean* temperature produced by solar radiation when the rays enter the earth's atmosphere will be

$$\frac{81^\circ \cdot 11 + 86^\circ \cdot 73}{2} = 83^\circ \cdot 92 \text{ F.},$$

while the temperature produced by the sun's radiant heat is only 81°·11 during the summer solstice, as before shown. Hence the temperature of the lunar surface when presented to the sun while the earth is furthest from the luminary can only be augmented 81°·11 F.

The remarkable fact that the moderate heat produced by solar radiation is capable of increasing the temperature of bodies previously heated to a high degree demands consideration in connection with the subject under investigation; also the nature of the device, before referred to, for ascertaining the temperature produced by solar radiation. The accompanying illustration

represents a combination of said device and a pyrheliometer differing materially from Pouillet's instrument, by showing the true intensity of the "fire" in the sun's rays.

The illustration presents a top view and a vertical section of the new instrument through the centre line. The upper part, composed of bronze, is cylindrical with a flat top, the bottom being semispherical, composed of ordinary glass. The top of the cylindrical chamber is provided with three circular perforations covered by a thin crystal carefully ground and polished. A thermometer having a spherical bulb is introduced through the side of the chamber, the bulb being central to the transparent semispherical bottom. A short parabolic reflector, shown in section on the illustration, surrounds the instrument, adjusted so that its focus coincides with the centre of the bulb of the thermometer. The compound cylindrical and spherical chamber is inclosed in a vessel containing water, appropriate openings at top and bottom being provided for maintaining constant circulation during experiments. Efficient means are also provided for exhausting the air from the internal chamber. The instrument is secured to the top of a substantial table which, during experiments, faces the sun at right angles by the intervention of a parallactic mechanism. Movable shades are applied, by means of which the sun's rays may be quickly cut off from, or admitted to, the parabolic reflector; while other shades enable the operator to admit or exclude the solar rays from the circular perforations at the top of the exhausted chamber. It will be readily understood that the parallel lines within the exhausted chamber, shown on the illustration, indicate the course of the solar rays passing through the crystal and the perforations at the top, while the converging radial lines indicate the rays reflected by the parabolic reflector. The upper hemisphere of the thermometric bulb, it will be seen, receives the radiant energy of the sun's rays which pass through the large central perforation; while the lower half of the bulb will be acted upon by the rays passing through the small perforations. These rays are reflected upwards by two inclined circular mirrors attached to the bottom of the exhausted chamber. It should be particularly observed that the areas of these inclined mirrors *together* should exceed the area of the great circle of the bulb of the thermometer sufficiently to make good the loss of radiant energy caused by the imperfect reflection of the said mirrors, and also to make good the loss attending the passage of the solar rays through the crystal. A capacious water cistern, connected by flexible tubes with the external casing of the pyrheliometer, enables the operator to maintain the exhausted chamber at any desirable temperature. Engineers of great experience in the application of heat for the production of motive power and other purposes deny that the temperature of a body can be increased by the application of heat of a lower degree than that of the body whose temperature we desire to augment. The soundness of their reasoning is apparently incontrovertible, yet the temperature of the mercury in the instrument just described raised to 600° F. by means of the parabolic reflector, increases at once when solar heat is admitted through the circular apertures, although the sun's radiant intensity at the time may not reach one-tenth of the stated temperature. It should be mentioned that the trial of this new pyrheliometer has not been concluded, owing to very unfavourable atmospheric conditions since its completion. For our present purpose the great fact established by the illustrated instrument is sufficient, namely that the previous temperature of a body exposed to the sun's radiant heat is immaterial. The augmentation of temperature resulting from exposure to the sun, the pyrheliometer shows, depends upon the intensity of the sun's rays.

Regarding the temperature prevailing during the lunar night, its exact degree is not of vital importance in establishing the glacial hypothesis, since the periodical increment of temperature produced by solar radiation is only a fraction of the permanent loss attending the continuous radiation against space resulting from the absence of a lunar atmosphere; besides, all physicists admit that it is extremely low. Sir John Herschel says of the night temperature of the moon that it is "the keenest severity of frost, far exceeding that of our Polar winters." Proctor says: "A cold far exceeding the intensest ever produced in terrestrial experiments must exist over the whole of the unilluminated hemisphere." The author of "Outlines of Astronomy" has also shown that the temperature of space, against which the moon at all times radiates, is -151° C. ($-239^\circ\!\cdot\!8$ F.), Pouillet's estimate being -142 C. ($-223^\circ\!\cdot\!6$ F.). Adopting the latter degree, and allowing $81^\circ\!\cdot\!1$ for the sun's radiant heat, we establish the fact that the temperature of the lunar surface presented to the sun will be $223^\circ\!\cdot\!6$ less $81^\circ\!\cdot\!1$, or -142° 5 F., when the earth is in aphelion. It will be well to bear in mind that when the earth is in the said position, the sun's rays acting on the moon subtend an angle of 31′ 32″, hence the loss of heat by radiation against space will be diminished only 0·000021 during sunshine. Nor should Herschel's investigation be lost sight of, showing that stellar heat bears the same proportion to solar heat as stellar light to solar light. Stellar heat being thus practically inappreciable, the temperature produced by stellar radiation cannot be far from absolute zero—an assumption in harmony with the views of those who have studied the subject of stellar radiation, and consequently regard Pouillet's and Herschel's estimate of the temperature of space as being much too high.

Having disposed of the question of temperature, let us return to the practical consideration of the glacial hypothesis. The formation of annular glaciers by the joint agency of water and the internal heat of a planetary body devoid of an atmosphere and subjected to extreme cold is readily explained on physical principles. Suppose a sheet of water, or pond, on the moon's surface, covering the same area as the plateau of Tycho, viz. 50 miles diameter and 1960 square miles. Suppose, also, that the internal heat of the moon is capable of maintaining a moderate steam pressure, say 2 lbs. to the square inch, at the surface of the water in the pond. The attraction of the lunar mass being only one sixth of terrestrial attraction, while the moon's surface is freed from any atmospheric pressure, it will be evident that under the foregoing conditions a very powerful ebullition and rapid evaporation will take place, and that a dense column of vapour will rise to a considerable height above the boiling water. It will also be evident that the expansive force within this column at the surface of the water will be so powerful at the stated pressure that the vapour will be forced beyond the confines of the pond in all directions with great velocity. No vertical current, it should be understood, will be produced, since the altitude of the column, after having adjusted itself to the pressure corresponding with the surface temperature of the water, remains stationary, excepting the movement consequent on condensation from above. The particles of vapour forced beyond the confines of the pond, on being exposed to the surrounding cold, caused by unobstructed radiation against space, will of course crystallise rapidly, and in the form of snow fall in equal quantity round the pond, and thereby build up an annular glacier. As the radius of the vaporous column exceeds 25 miles, it will be perceived that, notwithstanding the rapid outward movement, before referred to, some of the snow formed by the vapours rising from the boiling pond will fall into the same, to be melted and re-evaporated.

In connection with the foregoing explanation of the formation of annular glaciers, their exact circular form demands special consideration. An examination of Rutherford's large photograph of the lunar surface shows that, apart from the circular form of the walls, the bottoms of the depressions are in numerous cases smooth, rising slightly towards the centre uniformly all round. The precision observable proves clearly the action of formative power of great magnitude. Referring to what has already been explained regarding the vaporous column of 25 miles radius, calculation shows that a surface temperature exerting the moderate pressure of 2 lbs. to the square inch will produce an amount of mechanical energy almost incalculable. Practical engineers are aware that the steam rising from a surface of water 10 square feet, heated by a very slow fire, is capable of producing an energy of 1 horse-power; consequently a single square mile of the boiling pond will develop 2,780,000 horse-power. This prodigious energy will obviously be exerted *horizontally*, as the weight of the superincumbent column of vapour balances its *expansive* force precisely as the weight of our atmosphere balances its expansive force. But unlike the earth's atmosphere, which is restrained from horizontal movement by its continuance round the globe, the vapour of the column of 50 miles diameter is free to move beyond the confines of the pond. A very powerful horizontal motion, especially of the lower part of the vaporous mass, will thus be promoted, acting in radial lines from the centre, the principal resistance encountered being the friction against the water. Considering that the friction against the surface of the ocean, caused by the gentle trade-wind, is sufficient to produce the Gulf Stream, we need no figures to show the effect on the water in the boiling pond produced by the vaporous mass propelled by an energy of 2 lbs. to the square inch, in radial lines towards its confines. A circular tidal wave of extraordinary power, together with a return under-current towards the centre, will obviously be the result. But agreeably to the laws supposed to govern vortex

motion, these currents cannot be maintained in a radial direction. A rotary motion, rapidly augmenting, will take place, producing a vortex more powerful than any imagined by Descartes. The radial currents of the vaporous column having assumed a spiral course, will rapidly acquire a velocity exceed that of a cyclone. The practical effect of the powerful movement of the vortex, it is reasonable to suppose, will resemble that of a gigantic carving-tool whose thorough efficiency in removing irregularities has been proved by the exact circular outline presented by thousands of lunar formations. The terraces within the "ring mountains" indicated on Beer and Mädler's chart, it may be shown, were produced by evaporation resulting from low temperature and reduced energy after the formation of the main glacier.

There is another feature in the lunar landscape scarcely less remarkable than its circular walls and depressions. In the centre of nearly all of the latter one or more conical hills rise, in some cases several thousand feet high. Has the rotary motion of the boiling vortex any connection with these central cones? A brief explanation will show that the connection is quite intimate. The under-rated estimate that 10 square feet of surface under the action of slow fire is capable of developing one horse-power proves the presence of a dynamic energy exceeding 5,000,000,000 of horse-power at the base of the vaporous column resting on the boiling water of a pond as large as that of Tycho. No part of this power can be exerted vertically, as already explained, on the ground that the weight of the vapour restrains such movement. The great velocity of the vortex resulting from the expenditure of the stated amount of dynamic energy will of course produce corresponding centrifugal force; hence a maelström will be formed capable of draining the central part of the pond, leaving the same dry, unless the water be very deep, in which case the appearance of a dry bottom will be postponed until a certain quantity of water has been transferred to the glacier. It should be observed that the central part of the bottom, freed from water, will also be freed from the surrounding cold by the protection afforded by the vaporous mass. The quantity of snow formed above the centre, at great altitude, will be small, and of course diverged during the fall. Evidently the dry central part, prevented, as shown, from cooling, will soon acquire a high temperature, admitting the formation of a vent for the expulsion of lava, called for as the moon, whose entire dry surface is radiating against space, shrinks rapidly under the forced refrigeration attending glacier-formation. Lava-cones similar to those of terrestrial volcanoes, and central to the circular walls, may thus be formed, the process being favoured by the feebleness of the moon's attraction. The existence of warm springs on the protected central plains is very probable; hence the formation of cones of ice might take place during the last stages of glacier-formation, when those plains no longer receive adequate protection against cold.

In accordance with the views expressed in the monograph read before the American Academy of Science, continued research has confirmed my supposition that the water on the moon bears the same proportion to its mass as the water of the oceans to the terrestrial mass I have consequently calculated the contents of the circular walls of the "ring mountains" measured and delineated by Beer and Mädler, and find that these walls contain 630,000 cubic miles. The opposite hemisphere of the moon being subjected to similar vicissitudes of heat and cold as the one presented to the earth, the contents of the circular walls not seen cannot vary very much from those recorded in "Der Mond"; hence the total will amount to 1,260,000 cubic miles. Allowing for the difference of specific gravity of ice, the stated amount represents 1,159,000 cubic miles of water. But "Der Mond" does not record any of the minor circular walls which, as shown by the large photograph before referred to, cover the entire surface of some parts of the moon. On careful comparison it will be found that the contents of the omitted circular formations is so great that an addition of 50 per cent. to the before-stated amount is called for. An addition of 25 per cent. for the ice-fields, whose extent is indicated by cracks and optical phenomena, is likewise proper. The sum total of water on the moon, therefore, amounts to 2,028,600 cubic miles.

Adopting Herschel's estimate of the moon's comparative mass, viz. 0·011364, and assuming that the oceans of the earth cover 130,000,000 square miles, it will be seen that the estimated quantity of water on the moon corresponds with a mean depth of 7250 feet of the terrestrial oceans.[1] This depth agrees very nearly with the oceanic mean depth established by the soundings for the original Atlantic cable, viz. 7500 feet; but the result of the *Challenger* Expedition points to a much greater depth. This circumstance is by no means conclusive against the supposition that the satellite and the primary are covered with water in relatively equal quantities. The correctness of Sir John Herschel's demonstration proving the tendency of the water on the lunar surface to flow to the hemisphere furthest from the earth must be disproved before we reject the assumption that the quantity of water on the surface of the moon bears the same proportion to its mass as the quantity of water on the earth to the terrestrial mass.

JOHN ERICSSON

[1] $\frac{2028600 \times 5280}{130000000 \times 0·011364} = 7250$ feet mean depth of terrestrial oceans corresponding with water on the moon.

SCIENTIFIC SERIALS

Rendiconti del Reale Istituto Lombardo, May 27.—Determination of the heat of fusion in the alloys of lead, tin, bismuth, and zinc, by Prof. D. Mazzotto. By the cooling process usually adopted for determining the specific heat of liquids, the author finds the point of fusion and the heat of fusion for these various chemical alloys as under:—

	Point of fusion	Heat of fusion
Tin and lead	181°	10°29
Tin and zinc	196	16·20
Tin and bismuth	138	11·065
Bismuth and lead	126	4·744

Two of these coincide and two others differ little from the composition of the chemical alloys as given by Rudberg.—Education and crime in Italy, by S. Amato Amati. In order to ascertain the influence of public instruction on the criminal classes in the Peninsula, the author has compiled a number of comparative tables based on official returns ranging from the year 1871 to 1883 inclusive. For the last three years of this period the results are as under:—

	Criminals	Unlettered	Could read and write	Educated
1881	8693	5511	3031	151
1882	7009	4139	2671	199
1883	6490	3741	2596	153

According to the three last census returns the total percentage of unlettered was as under:—

	Males	Females	Total
1861	65·47	81 52	73·50
1871	60·16	77·18	68·64
1881	53·89	72·93	63·45

—Meteorological observations made at the Brera Observatory, Milan, during the month of May.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 6.—"Further Discussion of the Sun-spot Spectra Observations made at Kensington." By J. Norman Lockyer. Communicated to the Royal Society by the Solar Physics Committee.

I have recently discussed, in a preliminary manner, the lines of several of the chemical elements most widened in the 700 spots observed at Kensington.

The period of observation commences November 1879, and extends to August 1885. It includes, therefore, the sunspot curve from a minimum to a maximum and some distance beyond.

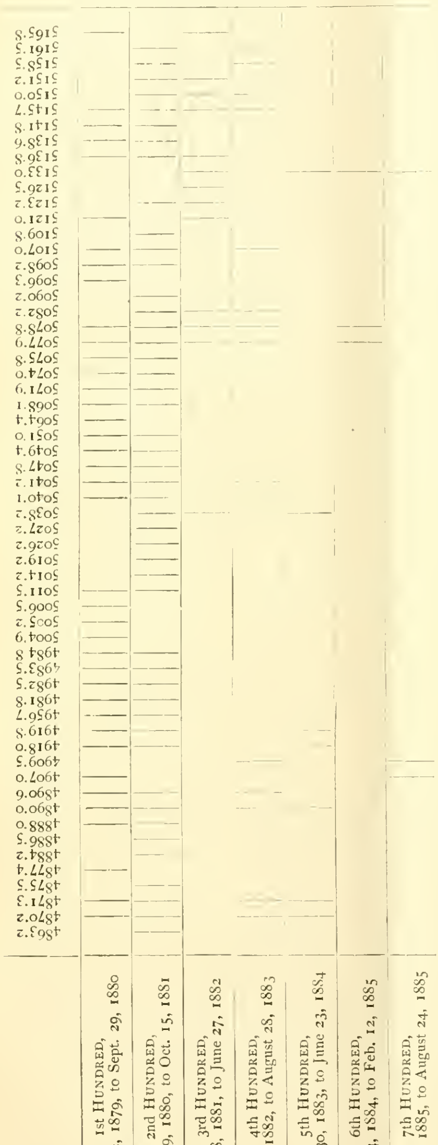
It is perhaps desirable that I should here state the way in which the observations have been made. The work, which has been chiefly done by Messrs. Lawrance and Greening, simply consists of a survey of the two regions F—*b* and *b*—D.

The most widened line in each region—not the widest line, but the *most widened*, is first noted; its wave-length being given in the observation books from Angström's map. Next, the lines which most nearly approach the first one in widening are recorded, and so on till the positions of six lines have been noted, the wave-lengths being given from Ångström's map, for each region.

It is to be observed that these observations are made without any reference whatever to the origin of the lines; that is to say it is no part of the observer's work to see whether there are metallic coincidences or not; this point has only been inquired into in the present reductions, that is, seven months after the

TABLE A.—IRON

Iron Lines observed in Sunspot Spectra at Kensington among the most Widened Lines



last observations now discussed were made. In this way perfect absence of all bias is secured.

It may further be remarked that the number of lines widened throughout a sunspot period is about the same, so that the conditions of observation vary very little from month to month, and from year to year.

It may be further remarked that the absolute uniformity of the results obtained in the case of each of the chemical elements investigated indicates, I think, that the observations have been thoroughly well made; and, as a matter of fact, they are not difficult.

I first give tables (A, B, C) showing that for each of the

TABLE B.—NICKEL

List of most Widened Lines observed at Kensington

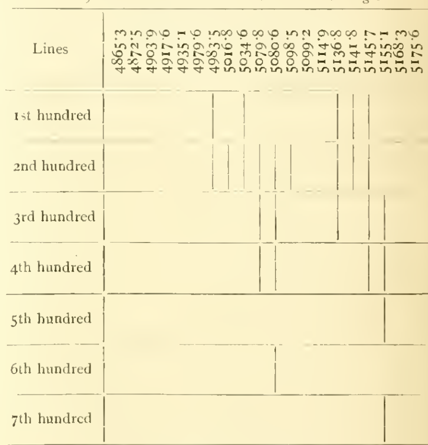


TABLE C.—TITANIUM

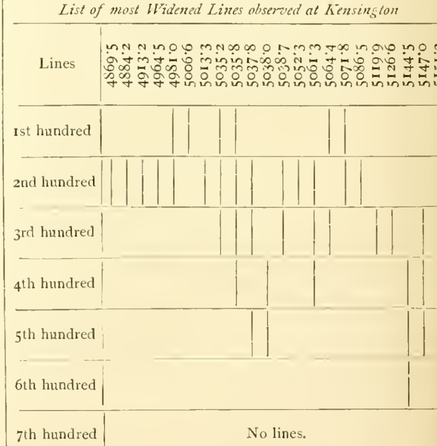
List of most Widened Lines observed at Kensington



chemical elements taken—iron, nickel, and titanium—the num- of lines seen in the aggregate in each hundred observations is reduced from minimum to maximum, and that this result holds good for both regions of the spectrum.

I next give another table (D) showing that during the obser-

vations the lines recorded as most widened near the maximum have not been recorded amongst metallic lines by either Ångström or Thalèn, and that many of them are not among the mapped Fraunhofer lines, though some of them may exist as faint lines in the solar spectrum when the observing conditions are best.

The reduction of the latitudes of the spots is not yet completed.

The result of these observations may be thus briefly stated. As we pass from minimum to maximum, the lines of the chemical elements gradually disappear from among those most widened, their places being taken by lines of which at present we have no terrestrial representatives. Or, to put the result another way—at the minimum period of sunspots when we know the solar atmosphere is quietest and coolest, vapours containing the lines of some of our terrestrial elements are present in sunspots. The vapours, however, which produce the phenomena of sunspots at the sunspot maximum are entirely unfamiliar to us.

The disappearance of the lines of iron, nickel, and titanium, and the appearance of unknown lines as the maximum is reached, is shown by curves in Fig. 1.

The results, in my opinion, amply justify the working hypothesis as to the construction of the solar atmosphere which I published some years ago (*Proc.* Roy. Soc., 1882, p. 291). In the region of the spectrum comprised between 4860 and 5160, I find in the case of iron, to take an instance, that sixty lines were distributed unequally among the spots in 1879 and 1880, many iron lines being visible in every spot. In the last observations, about the maximum, only three iron lines in all are seen among the most widened lines. These three lines also have been visible in four spots only out of the last hundred. The same thing happens with titanium and nickel, and with all the substances for which the reductions are finished.

I am quite content, therefore, to believe that iron, titanium, nickel, and the other substances very nearly as complex as we know them here, descend to the surface of the photosphere, in the downrush that forms a spot at the period of minimum, but that at the maximum, on the contrary, only their finest constituent atoms can reach it. It may also be remarked that these particles which survive the dissociating energies of the lower strata are not the same particles among the constituents of the chemical elements named which give the chromospheric lines recorded by Tacchini, Riccò, and myself.

Having thus found the working hypothesis to which I have referred stand the severe test which the sunspot observations apply to it, I have gone further, and have endeavoured to extend it in two directions.

First. I found that the view to which the hypothesis directly leads, that the metallic prominences are produced by violent explosions due to sudden expansions among the cooler matters brought down to form the spots, when they reach the higher temperature at and below the photosphere level, includes all the facts I know touching spot and prominence formation. Thus, for instance, the close connection between metallic prominences and spots; the entire absence of metallic prominences with rapid motion from any but the spot-zones; the fact that the faculæ always follow the formation of a spot and never precede it; that the faculous matter lags behind the spot as a rule; the existence of veiled spots and minor prominences in regions outside the spot-zones; the general injection of unknown substances into the lower levels of the chromosphere which I first observed in 1871, and which have been regularly recorded by the Italian observers since that time—all these phenomena and many others which may be referred to at length on another occasion, are demanded by the hypothesis, and are simply and sufficiently explained by it.

With regard to the extensions of volume to which I have re-

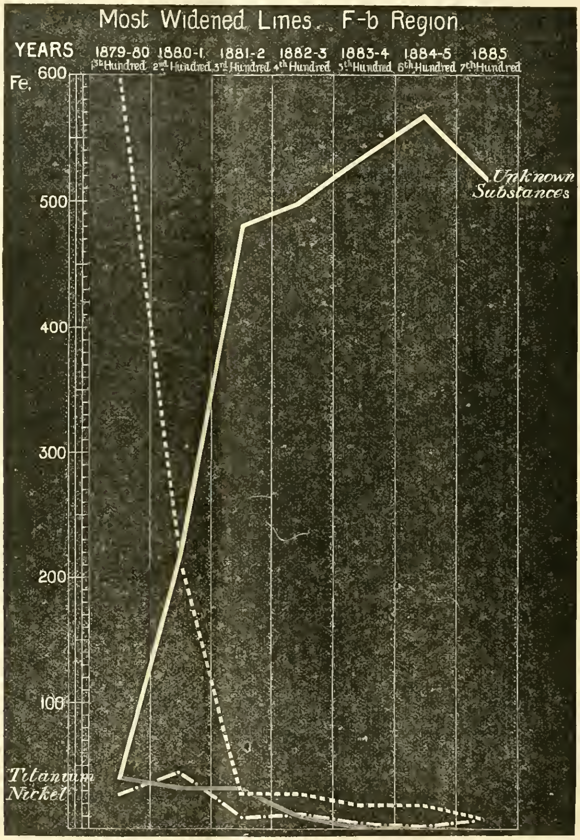

Fig. 1.—Number of appearances of known aod unkoown lines.

ferred, I find that if we assume that metallic iron can exist in any part of the sun's atmosphere, and that it falls to the photosphere to produce a spot, the vapour produced by the fall of 1,000,000 tons will give us the following volumes:—

Temperature		Pressure		Volume in cubic miles
2,000° C.	...	380 mm.	...	0·8
10,000	...	760 ,,	...	1·8
20,000	...	5 atmos.	...	0·7
50,000	...	760 mm.	...	8·8
50,000	...	190 ,,	...	35·2

If we assume the molecule of iron to be dissociated ten times by successive halving, then the volume occupied will be 1024 times greater, and we shall have—

Temperature		Pressure		Volume in cubic miles
50,000° C.	...	760 mm.	...	9,011
50,000	...	190 ,,	...	36,044

In these higher figures we certainly do seem nearer the scale on which we know solar phenomena to take place; the tremendous rending of the photosphere, upward velocities of 250 miles a second, and even higher horizontal velocities according to

Peters, are much more in harmony with the figures in the second table than the first.

I may mention, in connection with this part of the subject, that the view of the great mobility of the photosphere which this hypothesis demands, so soon as we regard metallic prominences as direct effects of the fall of spot material, is further justified by the fact that, if we assume the solar atmosphere, that is the part of the sun outside the photosphere, to be about 500,000 miles high, which I regard as a moderate estimate, the real average density of the sun is very nearly equal to one-tenth that of water, instead of being slightly greater than that of water, as stated in the text-books.[1]

We can then only regard the photosphere as a cloudy stratum existing in a region of not very high pressure. It is spherical because it depends upon equal temperatures.

The second direction in which I have attempted to develop the hypothesis has relation to the circulation in the sun's atmosphere. I have taken the facts of the solar atmosphere as a whole, as they are recorded for us in the various photographs taken during eclipses since 1871, and also in drawings made before that time, the drawings being read in the light afforded by these photographs.

I find that the working hypothesis at once suggests to us that the sunspot period is a direct effect of the atmospheric circulation, and that the latitudes at which the spots commence to form at the minimum, which they occupy chiefly at the maximum, and at which they die out at the end of one period in one hemisphere, probably at the moment they commence to form a second one in the other (as happened in 1878–79), are a direct result of the local heating produced by the fall of matter from above descending to the photosphere, and perhaps piercing it. The results of this piercing are the liberation of heat from below and various explosive effects due to increase of volume, which, acting along the line of least resistance, give, as a return current, incandescent vapours ascending at a rate which may be taken as a maximum of 250 miles a second, a velocity sufficient to carry them to very considerable heights.

The view of the solar circulation at which I have arrived may be briefly stated as follows :—

There are upper outflows from the poles towards the equatorial regions. In these outflows a particle constantly travels, so that its latitude decreases and its height increases, so that the true solar atmosphere resembles the flattened globe in Plateau's experiment (see photographs, 1878, and Fig. 3).

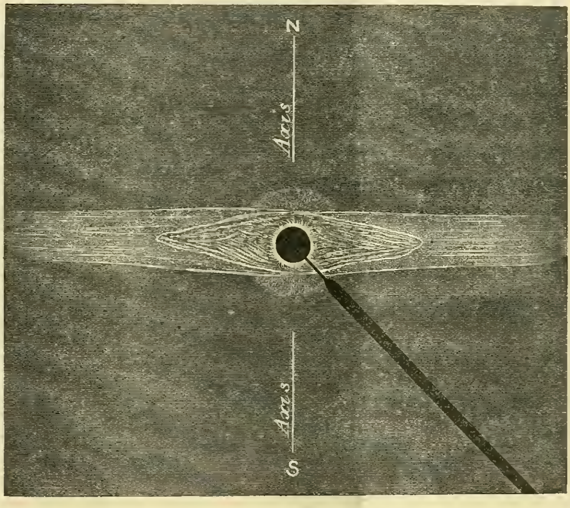

FIG. 2.—Minimum. Tracing of Newcomb's observation of 1878, the brighter portion of corona being hidden by a screen. Shows the equatorial extension and concentric atmospheres.

These currents, as they exist in the higher regions of the atmosphere, carry and gather the condensing and condensed materials till at last they meet over the equator.

There is evidence to show that they probably extend as solar meteoric masses far beyond the limits of the true atmosphere, and form a ring, the section of which widens towards the sun, and the base of which lies well within the boundary of the atmosphere (Fig. 2).

If we assume such a ring under absolutely stable conditions, there will be no disturbance, no fall of material, therefore there will be no spots, and therefore again there will be no prominences. Such was the state of things on the southern surface of the ring from December 1877 to April 1879, during which period there was not a single spot observed the umbra of which was over 15-millionths of the sun's visible hemisphere.

Assume a disturbance. This may arise from collisions, and these collisions would be most likely to happen among the particles where the surface of the ring meets the current from the poles. These particles will fall towards the sun, thereby disturbing and arresting the motion of other particles nearer the photosphere, and finally they will descend with a crash on to the photosphere, from that point where the surface of the ring enters the atmosphere some distance further down.

The American photographs in 1878 supply us with ample evidence that this will be somewhere about lat. 30°, and here alone will the first spots be formed for two reasons.

(1) In the central plane of the ring over the equator, the particles will be more numerous ; a rapid descent, therefore, in this central plane will be impossible, for the reason that the condensed matter has to fall perhaps a million of miles through strata of increasing temperature ; there will, therefore, be no spots ; and practically speaking, as is known, there are no spots at the equator, though there are many small spots without umbræ between latitudes 3° and 6° N. and S.

Above lat. 30°, as a rule, we have no spots, because there is no ring, and further the atmosphere is of lower elevation, so that there is not sufficient height of fall to give the velocities require to bring down the material in the solid form.

The lower corona, where the corona is high, and it is highest over the equator, acts as a shield or buffer ; volatilisation and

[1] The density referred to water = 1·444 and to the earth 0·255, according to Newcomb.

dissociation take place at higher levels. Where this occurs, spots are replaced by a gentle rain of fine particles slowly descending, instead of the fall of mighty masses and large quantities of solid and liquid material.

Volatilisation will take place gradually during the descent, and at the utmost only a veiled spot will be produced.

We know that when the solar forces are weak, such a descent is taking place all over the sun, because at that time the spectrum of the corona, instead of being chiefly that of hydrogen, is one of a most complex nature—so complex that before 1882 it was regarded by everybody as a pure continuous spectrum, such as is given by the limelight.

The moment the fall of spot material begins we get the return current in the shape of active metallic prominences, and the production of cones and horns which probably represent the highest states of incandescence over large areas and extending to great heights; and, besides these, the production of streamers (see Fig. 4).

Two results follow:—

(1) In consequence of the increased temperature of the lower regions, the velocity of the lower currents towards the poles, and therefore of the upper currents from the poles, is enormously increased. The disturbance of the ring will therefore be increased.

(2) Violent uprushes of the heated photospheric gases, mounting with an initial velocity of a million miles an hour, can also disturb the ring directly.

In this way the sudden rise to maximum in the sunspot curve, and the lowering of the latitude of the spots, follow as a matter of course. And the part of the ring nearest the sun, its base, so to speak, is, it would appear, thrown out of all shape, and we get falls over broad belts of latitude N. and S.

Does this hypothesis explain, then, the slow descent to minimum and the still decreasing latitude? It does more, it demands it. For now the atmosphere over those regions where the spots have hitherto been formed is so highly heated and its height is so increased, that any disturbed material descending through it will be volatilised before it can reach the photosphere.

The best chance that descending particles have now to form spots is if they fall from points in lower latitudes. The final period, therefore, of the sunspot curve must be restricted to a very large extent to latitudes very near the equator, and this is the fact also, as is well known.

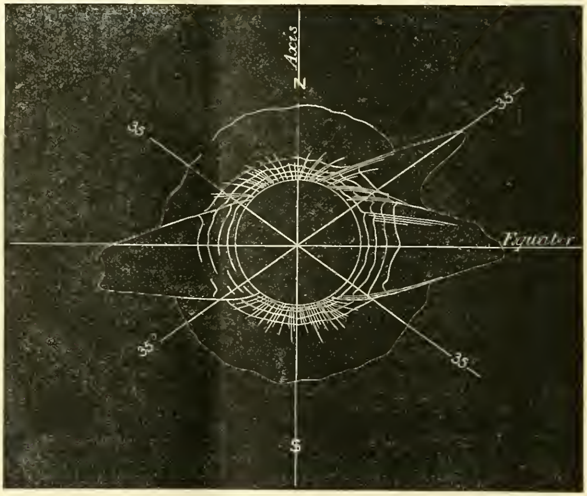

Fig. 3.—Minimum. Tracing of the results obtained by the cameras in 1878, showing inner portion of equatorial extension, and how the surfaces of it cut the concentric atmosphere in lat. 35° N. and S., or thereabouts.

It will be seen that on this view, as the brightness, and therefore the temperature, of the atmosphere, as we know, increases very considerably from minimum to maximum, the masses which can survive this temperature must fall from gradually increasing heights.

It may be pointed out how perfectly this hypothesis explains the chemical facts observed and associates them with those gathered in other fields of inquiry.

At the minimum the ring is nearest the sun, the subjacent atmosphere is low and relatively cool.

Particles falling from the ring, therefore, although they fall in smaller quantity because the disturbance is small, have the best chance of reaching the photosphere in the same condition as they leave the ring, hence at this time the widening in many familiar lines of iron, nickel, titanium, &c.

The gradual disappearance of these lines from the period of minimum to that of maximum is simply and sufficiently explained by the view that the spot-forming materials fall through gradually increasing depths of an atmosphere which at the same time is having its temperature as gradually increased by the result of the action I have before indicated, until finally, when the maximum is reached, if we assume dissociation to take place at a higher level at the maximum, dissociation will take place before the vapours reach the photosphere, and the lines which we know in our laboratories will cease to be visible.

This is exactly what takes place, and this result can be connected, as I have stated elsewhere, with another of a different kind. This hypothetical increasing height of fall demanded by the chemistry of the spots is accompanied by a known acceleration of spot movement over the sun's disk, as we lower the latitude—which can only be explained, so far as I can see, by a gradually increasing height of fall as the equator is approached.

There are two other points. (1) The sunspot curve teaches us that the slowing down of the solar activities at the maximum is very gradual. We should expect, therefore, the chemical conditions at the maximum to be maintained for some time afterwards. As a matter of fact, they have been maintained till March of the present year, and only now is a change taking place which shows us chemically that we are leaving the maximum conditions behind. (2) The disappearance of the lines of the metallic elements at maximum is so intimately connected with an enormous increase in the indications of the presence of

hydrogen that there is little doubt that we are in the presence of cause and effect. The hydrogen, I am now prepared to believe, is a direct consequence of the dissociation of the metallic elements.

It will be convenient to refer here to the facts which have been recorded during those eclipses which have been observed at the sunspot minimum and maximum.

At the minimum the corona is dim; observations made during the minimum of 1878 showed that it was only one-seventh as bright as the corona at the preceding maximum. There are no bright lines in its spectrum, and both photographic and eye-observations proved it to consist mainly of a ring round the equator, gradually tapering towards its outer edge, which some observations placed at a distance of twelve diameters of the sun from the sun's centre.

The same extension was observed in the previous minimum in 1867, and the polar phenomena were observed to be identical in both eclipses. At the poles there is an exquisite tracery curved in opposite directions, consisting of plumes or *panaches*, which bend gently and symmetrically from the axis, getting more and more inclined to it, so that those in latitudes 80° to 70° start nearly at right angles to the axis, and their upper portions droop gracefully, and curve over into lower latitudes.

Although indications of the existence of this ring have not been recorded during eclipses which have happened at the period of maximum, there was distinct evidence both in the eclipses in 1871 and 1875 of the existence of what I regard as the indications of outward upper polar currents observed at minimum.

The fact that the solar poles were closed at the maximum of 1882, while they were open in 1871, is one of the arguments which may be urged that at times the whole spot-zones are surmounted by streamers, with their bases lying in all longitudes along the zones.

It was probably the considerable extension of these streamers earthwards, in 1882, which hid the finer special details at the poles, while in 1871 the part of the sun turned towards the earth was not rich in streamers of sufficient extension.

Touching these streamers, it is an important fact to be borne in mind, that no spots ever form on the poleward side of them.

It is obvious, therefore, that spots are not produced by the condensation of materials on their upper surfaces, for in that case the spots would be produced indifferently on either side of them, and the width of the spot-zones would be inordinately increased.

Although in the foregoing I have laid stress upon the indications afforded by the observations of 1878 of the existence of a ring, it should be remarked that, so far, the eclipse appearances

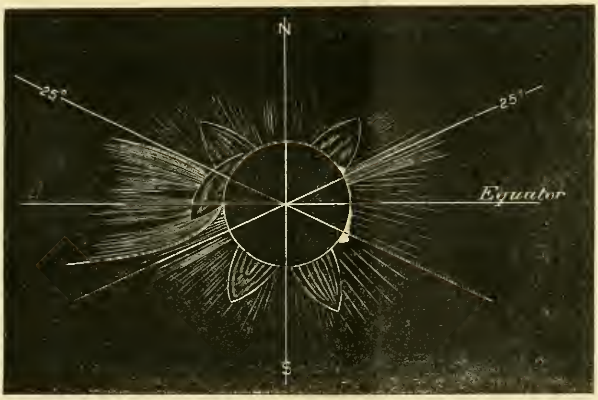

FIG. 4.—$1\frac{1}{2}$ years from maximum, 1858. Tracing of drawing by Liais, showing "cones."

on which the idea rests have not been observed at maximum. This, however, is not a fatal objection, because precautions for shielding the eye were necessary even in 1878 when the corona was dim; and if it is composed merely of cooled material it would not readily be photographed.

In may be urged by some that the phenomena observed in 1878 may only after all have been equatorial streamers.

It is obvious, therefore, that this point deserves the closest attention during future eclipses, until it is settled one way or the other.
